**Observation of the Higgs boson in the  $WW^*$  channel and search  
for Higgs boson pair production in the  $b\bar{b}b\bar{b}$  channel with the  
ATLAS detector**

**ABSTRACT**

We measured things. And searched for other things. Here is what we found, please let me graduate.

## Listing of figures

1.1	The particles of the Standard Model and their properties[1]. . . . .	4
1.2	The four most common Higgs boson production modes at the LHC: (a) gluon-gluon fusion, (b) vector boson fusion, (c) $W/Z + H$ production, (d) $t\bar{t}H$ production . . . . .	8
1.3	Higgs production cross sections as a function of center of mass energy ( $\sqrt{s}$ ) at a $pp$ collider[2]. . . . .	9
1.4	Higgs boson branching ratios as a function of $m_H$ [2]. . . . .	II
1.5	The two leading diagrams for Standard Model di-Higgs production at the LHC: (a) box diagram, (b) Higgs self coupling . . . . .	13
1.6	Diagrams with new vertices for non-resonant Higgs pair production arising in composite Higgs models . . . . .	14
1.7	Generic Feynman diagram for resonant Higgs pair production in BSM theories . . . . .	15
1.8	Branching ratios for a spin-2 Randall-Sundrum graviton as a function of mass computed in MadGraph with the CP <sub>3</sub> -Origins implementation [3, 4] . . . . .	16
1.9	$\sigma \times BR(HH)$ for RSG as a function of mass computed in MadGraph with the CP <sub>3</sub> -Origins implementation [3, 4] . . . . .	16
1.10	RSG width as a function of mass computed in MadGraph with the CP <sub>3</sub> -Origins implementation [3, 4] . . . . .	17
1.II	Branching ratios for heavy Higgs $H$ in Type I (left) and Type II (right) 2HDM models with $\tan \beta = 1.5$ and $\cos(\beta - \alpha) = 0.1(0.01)$ for Type I (Type II). [5] . . . . .	18
2.1	A schematic view of the LHC ring [6] . . . . .	20
3.1	Branching ratios for a $WW$ system. $q$ refers to quarks. $\ell$ can be either an electron or muon, and the leptonic branching ratios of the $\tau$ are included. For example, the $\ell\nu qq$ final state includes one $W$ decaying to $e\nu$ , $\mu\nu$ , or $\tau\nu$ . $\tau_h$ refer to hadronic decays of the $\tau$ . . . . .	26
3.2	Feynman diagram for Standard Model $WW$ production . . . . .	27
3.3	Feynman diagrams for top pair production (left) and $Wt$ production (right) . . . . .	28
3.4	An example Feynman diagram of $W + \text{jets}$ production . . . . .	28
3.5	An example Feynman diagram of $Z + \text{jets}$ production . . . . .	29
3.6	An illustration of the unique analysis signal regions[7] . . . . .	30
3.7	A graphical illustration of the $E_{T,\text{rel}}^{\text{miss}}$ calculation . . . . .	32
3.8	Predicted backgrounds (compared with data) as a function of $n_j$ (a and b) and $n_b$ (c) . . . . .	33
3.9	An event display of a $Z/\gamma^* + \text{jets}$ event illustrating the effect of pileup interactions . . . . .	34

3.10	The RMS of different missing transverse momentum definitions as a function of the average number of interactions per bunch crossing . . . . .	35
3.11	The difference between the true and reconstructed values of the missing transverse momentum (a) and $m_T$ (b) in a gluon fusion signal sample . . . . .	36
3.12	Comparison of $f_{\text{recoil}}$ distributions for $Z/\gamma^* + \text{jets}$ , $H \rightarrow WW^*$ , and other backgrounds with real neutrinos. . . . .	37
3.13	Signal significance as a function of required value for $f_{\text{recoil}}$ and $p_{T,\text{rel}}^{\text{miss}(\text{trk})}$ in the ggF $H \rightarrow WW^*$ with $n_j = 0$ . . . . .	38
4.1	Diphoton mass spectrum in 7 and 8 TeV data. Panel a) shows the unweighted data distribution superimposed on the background fit, while panel c) shows the data where each event category is weighted by its signal to background ratio. Panels b) and d) show the respective distributions with background subtracted[8]. . . . .	48
4.2	Four lepton invariant mass spectrum ( $m_{4\ell}$ ) in 7 and 8 TeV data compared to background estimate. A 125 GeV SM Higgs signal is shown in blue[8]. . . . .	50
4.3	$m_T$ distribution in the $H \rightarrow WW \rightarrow e\nu\mu\nu n_j \leq 1$ channels for 8 TeV data[8]. . . . .	52
4.4	Local $p_0$ distribution as a function of hypothesized Higgs mass for the $H \rightarrow ZZ^* \rightarrow 4\ell$ (a), $H \rightarrow \gamma\gamma$ (b), and $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$ (c) channels. Dashed curves show expected results, while solid curves show observed. Red curves are from 7 TeV data, blue curves from 8 TeV, and black curved combined[8]. . . . .	54
4.5	Combined 95% CL limits (a), local $p_0$ values (b), and signal strength measurement (c) as a function of Higgs mass[8]. . . . .	55
4.6	Comparison of measured signal strength $\mu$ for a 126 GeV Higgs in the 7 and 8 TeV datasets[8].	56
4.7	Two dimensional likelihood as a function of signal strength $\mu$ and Higgs mass $m_H$ [8]. . . . .	56
5.1	A comparison of the subleading lepton $p_T$ spectrum between VBF $H \rightarrow WW^*$ production and $t\bar{t}$ background . . . . .	58
5.2	Leading jet $\eta$ in VBF $H \rightarrow WW^*$ (red) and $t\bar{t}$ (black) . . . . .	67
5.3	Distributions of (a) $m_{jj}$ , (b) $\Delta y_{jj}$ , (c) $C_{\ell 1}$ , and (d) $\Sigma m_{\ell j}$ , for the VBF analysis. The top panels compare simulation and data, while the bottom panels show normalized distributions for all background processes and signal[7]. . . . .	69
5.4	A cartoon of the WW final state. Momenta are represented with thin arrows, spins with thick arrows. [7] . . . . .	70
5.5	Event display of a VBF candidate event[7]. . . . .	72
5.6	Distributions of $m_{\ell\ell}$ (top left), $\Delta\phi_{\ell\ell}$ (top right), and $m_T$ (bottom) for the VBF BDT analysis. These are plotted after all of the BDT pre-training selection cuts[7]. . . . .	73

5.7	Distributions of $m_{jj}$ (top left), $\Delta y_{jj}$ (top right), $\sum C_\ell$ (bottom left), and $\Sigma m_{\ell j}$ (bottom right) for the VBF BDT analysis. These are plotted after all of the BDT pre-training selection cuts[7]. . . . .	74
5.8	Distributions of $O_{\text{BDT}}$ for the VBF signal and associated backgrounds after the VBF pre-training selection[7]. . . . .	75
5.9	Distributions of $m_{jj}$ (a) and $O_{\text{BDT}}$ (b) in the VBF $n_b = 1$ top CR[7]. . . . .	78
5.10	Comparison of $m_{jj}$ shape in a same flavor $Z \rightarrow \ell\ell$ control region and the VBF cut-based signal region. . . . .	79
5.11	General illustration of the ABCD region definitions for $Z/\gamma^* \rightarrow \ell\ell$ background estimation. . . . .	80
5.12	Distribution of $m_{\text{T}2}$ in the $WW$ validation region of the VBF analysis[7]. . . . .	82
5.13	Extrapolation factors for the $W + \text{jets}$ estimate derived for muons (a) and electrons (b) as a function of lepton $p_T$ [7]. . . . .	84
5.14	Background composition in final VBF signal region[7]. . . . .	84
5.15	Variations in the top background extrapolation factor in the cut-based analysis due to PDF uncertainties, binned in $m_{\text{T}}$ . . . . .	87
5.16	Variations in the top background extrapolation factor in the cut-based analysis due to QCD scale uncertainties, binned in $m_{\text{T}}$ . . . . .	87
5.17	Postfit distributions in the cut-based VBF analysis. Panel (a) shows the one-dimensional $m_{\text{T}}$ distribution, while (b) shows the data candidates split into the bins of $m_{\text{T}}$ and $m_{jj}$ used in the final fit[7]. . . . .	91
5.18	Postfit distributions in the BDT VBF analysis[7]. . . . .	92
5.19	Overlap between cut-based and BDT VBF signal region candidates in the $m_{jj}$ - $m_{\text{T}}$ plane. . . . .	92
6.1	Post-fit $m_{\text{T}}$ distribution in the $n_j \leq 1$ regions[7]. . . . .	96
6.2	Best fit signal strength $\hat{\mu}$ as a function of hypothesized $m_H$ [7]. . . . .	98
6.3	Local $p_0$ as a function of $m_H$ [7]. . . . .	98
6.4	Likelihood as a function of $\mu_{\text{VBF}}/\mu_{\text{ggF}}$ [7]. . . . .	99
6.5	Likelihood scan as a function of $\mu_{\text{VBF}}$ and $\mu_{\text{ggF}}$ [7]. . . . .	100
6.6	Likelihood scan as a function of $\kappa_F$ and $\kappa_V$ [7]. . . . .	101
6.7	Comparison of signal strength measurements in different Higgs decay channels on ATLAS[9].	103

# Listing of tables

1.1	Production cross sections for a 125 GeV Higgs boson at $\sqrt{s} = 8$ TeV with scale and PDF uncertainties [2].	10
1.2	Branching ratios for a 125 GeV Higgs boson[2].	12
1.3	Possible channels for Higgs searches. Checkmarks denote the most sensitive production modes [10].	12
1.4	Production cross sections for pair production of a 125 GeV Higgs boson at $\sqrt{s} = 14$ TeV with total uncertainty [11]. The uncertainties include QCD scale and PDF variations as well as uncertainties on $\alpha_S$ .	13
2.1	Evolution of LHC machine conditions [12, 13]	22
3.1	A summary of backgrounds to the $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$ signal	29
4.1	Monte carlo generators used to model signal and background for the Higgs search[8].	45
4.2	A summary of selection efficiencies and expected resolutions for a 125 GeV Higgs in the $H \rightarrow ZZ \rightarrow 4\ell$ channel[8].	49
4.3	Summary of the expected and observed significance and measured signal strengths in the combined 7 and 8 TeV datasets for the Higgs discovery analysis[8].	53
5.1	Single lepton triggers used for electrons and muons. A logical “or” of the triggers listed for each lepton type is taken. Units are in GeV, and the $i$ denotes an isolation requirement in the trigger.	59
5.2	Di-lepton triggers used for different flavor combinations. The two thresholds listed refer to leading and sub-leading leptons, respectively. The di-muon trigger only requires a single lepton at level-1.	59
5.3	Trigger efficiency for signal events and relative gain of adding a dilepton trigger on top of the single lepton trigger selection. The first lepton is the leading, while the second is the sub-leading. Efficiencies shown here are for the ggF signal in the $n_j = 0$ category but are comparable for the VBF signal.	60
5.4	Monte Carlo samples used to model the signal and background processes[7].	61
5.5	$p_T$ dependent isolation requirements for muons. Muons are required to have the amount of calorimeter or track based cone sums be less than this fraction of their $p_T$ .	63

5.6	$p_T$ dependent requirements for electrons. Electrons are required to have the amount of calorimeter or track based cone sums be less than this fraction of their $E_T$ . . . . .	64
5.7	Event selection for the $n_j \geq 2$ VBF analysis in the 8 TeV cut-based analysis[7]. . . . .	71
5.8	Top normalization factors computed at each stage of the cut-based selection. Uncertainties are statistical only. . . . .	77
5.9	Top normalization factors computed for each bin of $O_{\text{BDT}}$ . Uncertainties are statistical only. . . . .	77
5.10	$Z/\gamma^* \rightarrow \tau\tau$ correction factors for the VBF cut-based analysis. Uncertainties are statistical only. . . . .	80
5.11	$Z/\gamma^* \rightarrow \ell\ell$ normalization factors for cut-based and BDT analyses. Uncertainties are statistical only. . . . .	81
5.12	Systematic uncertainties for various processes in the BDT analysis, given in units of % change in yield. Values are given for the most sensitive BDT bin (bin 3), except where noted with a *, in which case the uncertainty affect the normalization in all BDT bins. Empty entries indicate that the uncertainty is negligible or not applicable to this background. . . . .	86
5.13	Systematic uncertainties for various processes in the cut-based VBF analysis, given in units of % change in yield. Values are given for the low $m_{jj}$ signal region. . . . .	86
5.14	Composition of the post-fit uncertainties (in %) on the total signal ( $N_{\text{sig}}$ ), total background ( $N_{\text{bkg}}$ ), and individual background yields in the VBF analysis[7]. . . . .	89
5.15	Event selection for the VBF BDT analysis. The event yields in (a) are shown after the pre-selection and the additional requirements applied before the BDT classification (see text). The event yields in (b) are given in bins in $O_{\text{BDT}}$ after the classification[7]. . . . .	90
6.1	All signal regions definitions input into final statistical fit[7]. . . . .	95
6.2	Post-fit yields in the different ggF and VBF dedicated signal regions[7]. . . . .	96

THIS IS THE DEDICATION.

## The Physics of the Higgs Boson

This chapter presents an overview of the Standard Model of Particle Physics and in particular the physics of the Higgs boson. First, a brief overview of the Standard Model and its history are presented. Then, a description of the Higgs mechanism of electroweak symmetry breaking is given. Next, the physics of single Higgs boson production and decay is described. The Standard Model also allows for production of two Higgs bosons and this is detailed as well. Finally, di-Higgs production in two beyond the Standard Model (BSM) theories - Randall-Sundrum gravitons (RSG) and Two Higgs Doublet Models (2HDM) - is shown.

### 1.1 THE STANDARD MODEL OF PARTICLE PHYSICS

The Standard Model (SM) of Particle Physics is a quantum field theory describing the fundamental particles of nature and the forces that govern their interactions. Several comprehensive treatments of the SM already exist in the literature<sup>[1, 10, 14–17]</sup> and this section will not rehash those. Rather, this

section presents a brief overview of the SM particles and forces in order to define them for subsequent discussions.

The Standard Model consists of two primary categories of fundamental particles: fermions (spin 1/2 particles) and bosons (integer spin particles). The SM also describes three forces: electromagnetism, the weak nuclear force, and the strong nuclear force. Gravity is not included in the theory and is largely irrelevant at the scales currently probed by collider experiments. Within the fermions, there are both quarks (which interact via all three forces) and the leptons. The charged leptons interact via electromagnetic and weak interactions, while neutrinos (neutral leptons) interact only via the weak force. Within the bosons, there are the  $W^\pm$  and  $Z$  bosons (the mediators of the weak force), the gluon ( $g$ , the mediator of the strong force), and the photon ( $\gamma$ ), the mediator of the electromagnetic force. Finally, there is the Higgs boson, a fundamental spin-0 particle resulting from the Higgs mechanism of electroweak symmetry breaking. Figure 1.1 summarizes the fermions and bosons of the SM.

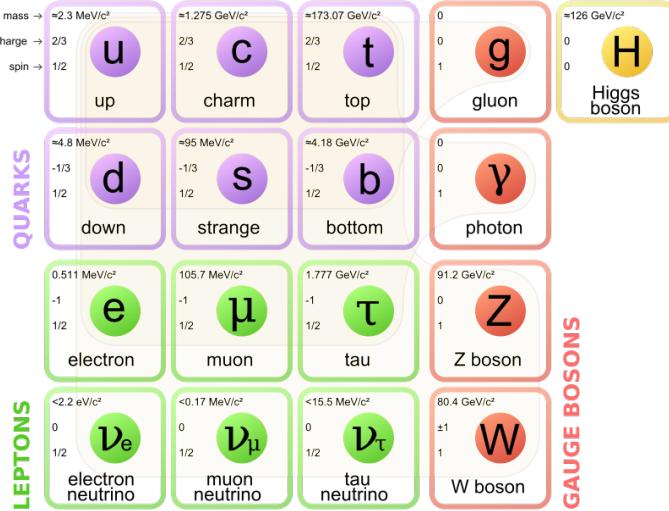

Figure 1.1: The particles of the Standard Model and their properties[1].

The Standard Model coalesced into a unified theoretical framework in the 1960s through the work of Glashow, Weinberg, Salam, and others on the theory of electroweak interactions[18–21]. This theory characterized both the electromagnetic and weak interactions as unified under a single gauge symmetry group, namely  $SU(2) \times U(1)$ . At low enough energy scales (on the order of the  $W$  and  $Z$  masses), the electroweak symmetry is broken, as evidenced by the fact that the weak bosons have mass while the

photon does not. The discovery of the Higgs boson in 2012 confirmed the Higgs mechanism as the most likely candidate for this electroweak symmetry breaking[8, 22]. The electroweak theory is then combined with the theory of quantum chromodynamics (which models the strong sector as a non-abelian  $SU(3)$  gauge group) to form the complete SM[23].

## 1.2 ELECTROWEAK SYMMETRY BREAKING AND THE HIGGS

In the Standard Model Lagrangian, it is difficult to include mass terms for the  $W$  and  $Z$  bosons without breaking the fundamental gauge symmetry of the Lagrangian. A traditional mass term does not preserve the  $SU(2) \times U(1)$  symmetry. Additionally, scattering of massive  $W$  and  $Z$  bosons violate unitarity and these diagrams diverge at high energy scales. In the 1960s, Higgs, Brout, Englert, Guralnik, Kibble, and Hagen developed a mechanism for spontaneous symmetry breaking via the addition of a complex scalar doublet to the SM. Three of the four real degrees of freedom of this complex field would go to the longitudinal modes of the  $W^\pm$  and  $Z$ , thus allowing them to have mass[24–27]. The remaining degree of freedom would manifest as an additional scalar, known now as the Higgs boson (Higgs was the first to predict the existence of the new particle).

The mechanism works by introducing a Lagrangian for the newly introduced field that still respects the symmetry of the Standard Model inherently, but with a minimum at a non-zero vacuum expectation value for the field. In this minimum of the potential, the electroweak symmetry is broken. Specifically, consider a complex scalar doublet  $\Phi$  with four degrees of freedom, as shown in equation 1.1.

$$\Phi = \begin{pmatrix} \phi^+ \\ \phi^0 \end{pmatrix} = \frac{1}{\sqrt{2}} \begin{pmatrix} \phi_1^+ + i\phi_2^+ \\ \phi_1^0 + i\phi_2^0 \end{pmatrix} \quad (1.1)$$

The minimal potential of a self-interacting Higgs that still respects the SM symmetry is given in equation 1.2.

$$V(\Phi) = \mu^2 \Phi^\dagger \Phi + \lambda (\Phi^\dagger \Phi)^2 \quad (1.2)$$

If the  $\mu^2$  term of this potential is positive, then the potential has a minimum at  $\Phi = 0$  and the SM

symmetry is preserved. However, if instead  $\mu^2 < 0$ , then the minimum is at a finite value of  $\Phi$ , namely

$$\Phi_{\min} = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ v \end{pmatrix} \quad (1.3)$$

where  $v = \sqrt{\mu^2/\lambda}$ . Because this is the location of the minimum, it corresponds to the vacuum expectation value for the field ( $\langle \Phi \rangle = \Phi_{\min}$ ). The excitations of the Higgs can then be parameterized as

$$\Phi = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ v + H \end{pmatrix} \quad (1.4)$$

The full scalar Lagrangian, including the kinetic term, is then given as

$$\mathcal{L}_s = (D^\mu \Phi)^\dagger (D_\mu \Phi) - V(\Phi) \quad (1.5)$$

where the covariant derivative is defined as

$$D_\mu = \partial_\mu + \frac{ig}{2} \tau^a W_\mu^a + ig' Y B_\mu \quad (1.6)$$

and  $W^1, W^2, W^3$  and  $B$  are the  $SU(2)$  and  $U(1)$  gauge fields of the electroweak theory, respectively.  $g$  and  $g'$  are the corresponding coupling constants. With the scalar Lagrangian in place, the physical gauge fields can then be written as

$$W_\mu^\pm = \frac{1}{\sqrt{2}} (W_\mu^1 \mp i W_\mu^2) \quad (1.7)$$

$$Z_\mu = \frac{-g' B_\mu + g W_\mu^3}{\sqrt{g^2 + g'^2}} \quad (1.8)$$

$$A_\mu = \frac{g B_\mu + g' W_\mu^3}{\sqrt{g^2 + g'^2}} \quad (1.9)$$

Equation 1.7 corresponds to the charged  $W^+$  and  $W^-$  bosons, equation 1.8 corresponds to the neu-

tral  $Z$  boson, and equation 1.9 corresponds to the neutral photon. The masses of the particles also arise from the Lagrangian. The photon has zero mass, while the masses of the  $W$  and  $Z$  bosons are given in equation 1.10.

$$\begin{aligned} M_W^2 &= \frac{1}{4}g^2v^2 \\ M_Z^2 &= \frac{1}{4}(g^2 + g'^2)v^2 \end{aligned} \tag{1.10}$$

The fermion masses also arise through a coupling with the Higgs via the Yukawa interaction (for a detailed description, see [17]). In this case the coupling between the Higgs and the fermions goes as

$$g_{Hf\bar{f}} = \frac{m_f}{v} \tag{1.11}$$

The full Lagrangian of Higgs interactions can be written as

$$\mathcal{L}_{\text{Higgs}} = -g_{Hf\bar{f}}\bar{f}fH + \frac{g_{HHH}}{6}H^3 + \frac{g_{HHHH}}{24}H^4 + \delta_V V_\mu V^\mu \left( g_{HVV}H + \frac{g_{HHV}}{2}H^2 \right) \tag{1.12}$$

with

$$\begin{aligned} g_{HVV} &= \frac{2m_V^2}{v} & g_{HHV} &= \frac{2m_V^2}{v^2} \\ g_{HHH} &= \frac{3m_H^2}{v} & g_{HHHH} &= \frac{3m_H^2}{v^2} \end{aligned} \tag{1.13}$$

Here,  $V$  refers to the  $W^\pm$  and  $Z$ , and  $\delta_W = 1$  while  $\delta_Z = 1/2$ . Phenomenologically, there are a few features of this Lagrangian that are useful to note. First, note that the Higgs mass is a free parameter of the theory that must be determined experimentally. Second, note that the coupling of the Higgs to the vector bosons and fermions scales with the masses of these particles, a fact that is important when considering both the production and decays of the particle. Also note that the branching ratio of the Higgs to  $W$  bosons will be twice that of the branching ratio to  $Z$  if the Higgs mass is large enough to produce the particles on shell because of the extra symmetry factor associated with the  $W$  coupling. Finally, note the presence of the cubic and quartic Higgs self interaction terms, which can lead to final

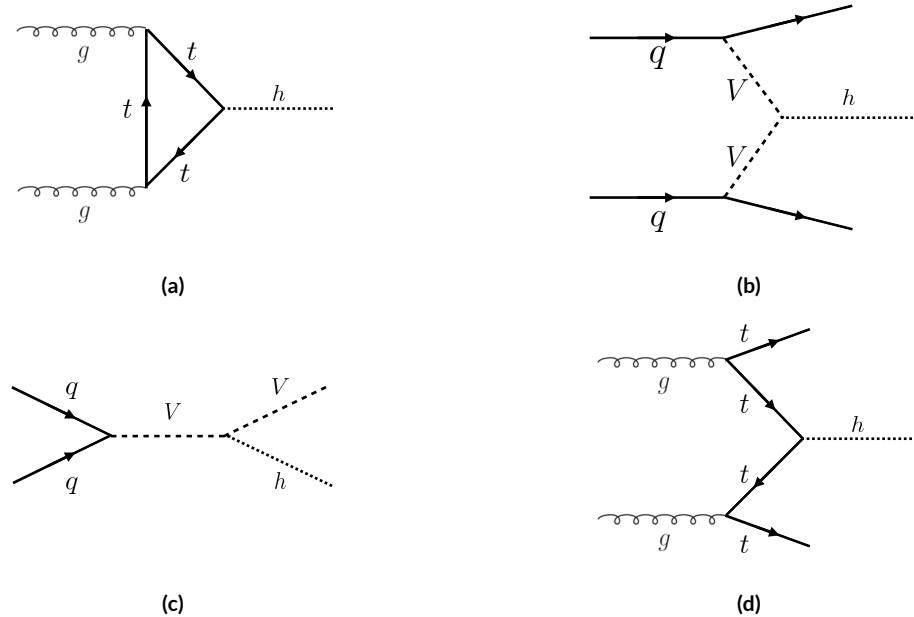

states with multiple Higgs bosons produced.

### 1.3 HIGGS BOSON PRODUCTION AND DECAY

This section discusses the properties of Higgs production and decay mechanisms. The details presented here will focus on the properties of a 125 GeV Higgs boson, as this is the mass closest to that of the newly discovered Higgs.

#### 1.3.1 HIGGS PRODUCTION

The Higgs is produced by four main production modes at the Large Hadron Collider - gluon-gluon fusion ( $ggF$ ), vector boson fusion (VBF), associated production with a  $W$  or  $Z$  boson, or associated production with top quarks ( $t\bar{t}H$ ). Figure 1.2 shows the Feynman diagrams for these four modes.

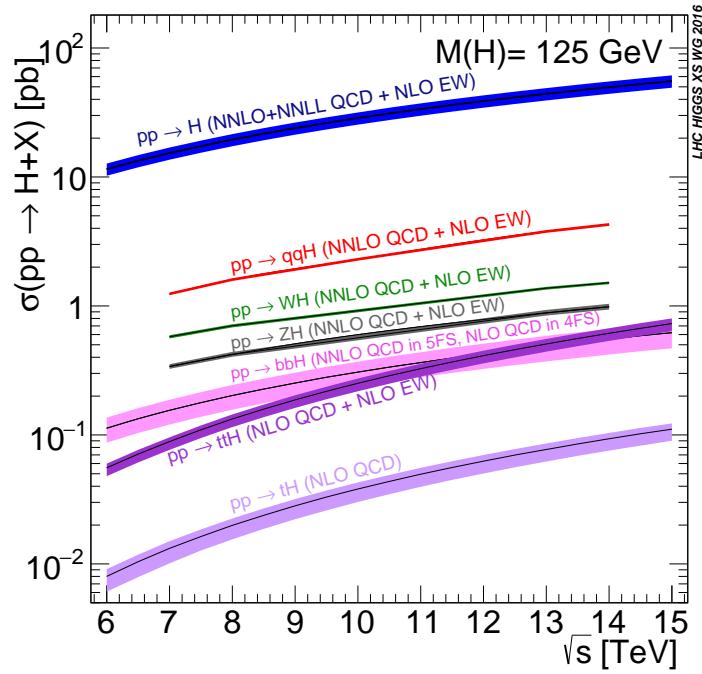

**Figure 1.2:** The four most common Higgs boson production modes at the LHC: (a) gluon-gluon fusion, (b) vector boson fusion, (c)  $W/Z + H$  production, (d)  $t\bar{t}H$  production

In gluon-gluon fusion, gluons from the incoming protons fuse via a top-quark loop to produce a Higgs. The top quark is the dominant contribution in the loop due to its heavy mass and the fact that the Higgs-fermion coupling constant scales with fermion mass. In vector boson fusion, the incoming

quarks each radiate a  $W$  or  $Z$  boson which fuse to produce the Higgs. This production mode results in a final state with a Higgs boson and two additional jets which tend to be forward because they carry the longitudinal momentum of the incoming partons. The Higgs can also be produced in association with a  $W$  or  $Z$  boson. The  $W/Z$  is produced normally and then radiates a Higgs (this mode is also sometimes known as “Higgs-strahlung”). Finally, the Higgs can be produced in association with two top quarks. Each incoming gluon splits into a  $t\bar{t}$  pair, and one of the top pairs combines to create a Higgs.

Figure 1.3 shows the production cross section for a 125 GeV Higgs boson in each of these modes at a  $pp$  collider as a function of center of mass energy.

**Figure 1.3:** Higgs production cross sections as a function of center of mass energy ( $\sqrt{s}$ ) at a  $pp$  collider[2].

In figure 1.3, note that gluon fusion has the largest cross section, while VBF is the second largest at approximately a factor of 10 smaller. The figure also includes the less commonly studied  $b\bar{b}H$  and  $tH$  modes. The  $b\bar{b}H$  and  $tH$  modes are not studied as commonly as  $t\bar{t}H$  due to the larger background contributions and lower cross sections, respectively. At  $\sqrt{s} = 8$  TeV, ggF production of a 125 GeV Higgs has a cross section of 19.47 pb, while VBF has a cross section of 1.601 pb[2]. The cross sections of all of the main Higgs production modes at this center of mass energy, as well as their uncertainties from

varying the renormalization and factorization scales and PDFs, are summarized in table 1.1 for a 125 GeV Higgs.

Production mode	$\sigma$ (pb)	QCD scale uncert. (%)	PDF + $\alpha_s$ uncert. (%)
Gluon fusion	19.47	+7.3 / - 8.0	3.1
Vector boson fusion	1.601	+0.3 / - 0.2	2.2
$WH$	0.7026	+0.6 / - 0.9	2.0
$ZH$	0.4208	+2.9 / - 2.4	1.7
$t\bar{t}H$	0.1330	+4.1 / - 9.2	4.3
$bbH$	0.2021	+20.7 / - 22.3	
$tH$ ( $t$ -channel)	0.01869	+7.3 / - 16.5	4.6
$tH$ ( $s$ -channel)	$1.214 \times 10^{-3}$	+2.8 / - 2.4	2.8

**Table 1.1:** Production cross sections for a 125 GeV Higgs boson at  $\sqrt{s} = 8$  TeV with scale and PDF uncertainties [2].

### 1.3.2 HIGGS BRANCHING RATIOS

The fact that the Higgs couples more strongly to more massive particles is crucial for understanding its branching ratios. The width for Higgs decays to fermions is given in equation 1.14 [10].

$$\Gamma(H \rightarrow f\bar{f}) = \frac{N_c \sqrt{2} G_F m_f^2 m_H}{8\pi} \quad (1.14)$$

In this case,  $N_c$  is the number of colors,  $G_F$  is the Fermi constant,  $m_f$  is the mass of the fermion, and  $m_H$  is the mass of the Higgs. Note that the width scales with the square of the fermion mass. (This also assumes that the Higgs mass is large enough to decay with both the fermions on shell.)

The decay width to  $WW$  is given in equation 1.15 [10].

$$\Gamma(H \rightarrow W^+W^-) = \frac{\sqrt{2} G_F M_W^2 m_H}{16\pi} \frac{\sqrt{1-x_W}}{x_W} (3x_W^2 - 4x_W + 4) \quad (1.15)$$

where  $m_W$  is the mass of the  $W$  and  $x_W = 4M_W^2/m_H^2$ . To get the branching ratio to  $ZZ$ , the equation is divided by 2 to account for identical particles in the final state, and  $x_W$  is replaced with

$x_Z = 4M_Z^2/m_H^2$ . This is shown in equation 1.16 [10].

$$\Gamma(H \rightarrow ZZ) = \frac{\sqrt{2}G_F M_Z^2 m_H}{32\pi} \frac{\sqrt{1-x_Z}}{x_Z} (3x_Z^2 - 4x_Z + 4) \quad (1.16)$$

These formulas can also be visualized as a function of Higgs mass. Figure 1.4 shows the branching ratios as a function of the Higgs mass.

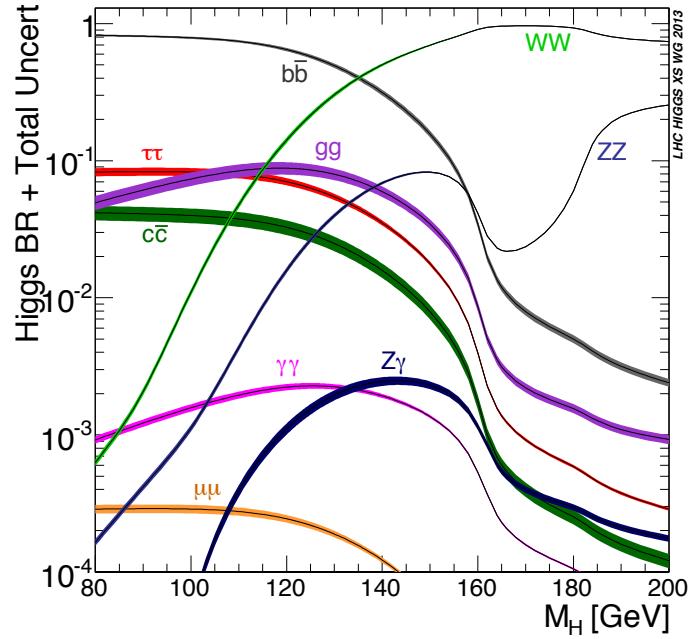

Figure 1.4: Higgs boson branching ratios as a function of  $m_H$  [2].

There are a few interesting features to note in this figure. First, note that at high Higgs masses, once on-shell production of both  $W$  and  $Z$  bosons is possible, these two decays are the dominant ones due to the large masses of the  $W/Z$ . Also note that the branching ratio to  $W$ s is twice that of  $Z$ s at these large masses due to the  $\delta_V$  symmetry factor noted previously. At 125 GeV, the Higgs is accessible through many different decay modes. The largest branching ratio is the decay  $H \rightarrow b\bar{b}$  at 58.24% [2]. This branching is larger than the  $WW/ZZ$  decays because one of the two bosons must be produced off-shell for  $m_H = 125$  GeV. The second largest branching ratio is to  $WW^*$  at 21.37 % (before taking into account the branching ratios of the  $W$ ). Table 1.2 summarizes the branching ratios for a 125 GeV Higgs. Note that there is in fact a Higgs branching ratio to  $\gamma\gamma$  even though photons are massless. This

decay happens through a loop (the largest contributions to the loop are top and  $W$ ) which suppresses the branching ratio.

Decay	Branching ratio (%)
$b\bar{b}$	58.24
$WW^*$	21.37
$gg$	8.187
$\tau\tau$	6.272
$c\bar{c}$	2.891
$ZZ^*$	2.619
$\gamma\gamma$	0.2270
$Z\gamma$	0.1533
$\mu\mu$	0.02176

**Table 1.2:** Branching ratios for a 125 GeV Higgs boson[2].

Note that the branching ratios alone do not tell the full story of which Higgs channels are the most sensitive. For example, a  $H \rightarrow b\bar{b}$  search in gluon fusion production is incredibly difficult due to the large QCD dijet background at the LHC. However, in associated production of the Higgs, where a  $W$  or  $Z$  gives additional final state particles that can be used to reduce background, a search for  $H \rightarrow b\bar{b}$  can be sensitive. The combinations of production and decay modes that are most commonly studied are summarized in table 1.3 [10].

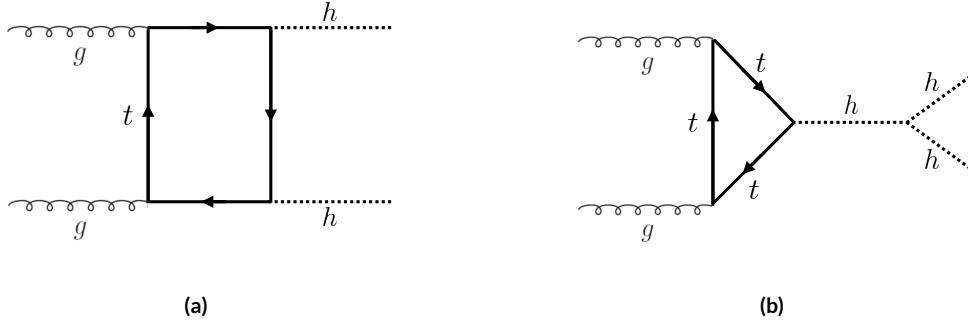

Decay	Inclusive (incl. ggF)	VBF	$WH/ZH$	$t\bar{t}H$
$H \rightarrow \gamma\gamma$	✓	✓	✓	✓
$H \rightarrow b\bar{b}$			✓	✓
$H \rightarrow \tau^+\tau^-$		✓		
$H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$	✓	✓	✓	
$H \rightarrow ZZ \rightarrow 4\ell$	✓			
$H \rightarrow Z\gamma \rightarrow \ell\ell\gamma$	very low			

**Table 1.3:** Possible channels for Higgs searches. Checkmarks denote the most sensitive production modes [10].

#### 1.4 HIGGS PAIR PRODUCTION IN THE STANDARD MODEL

The Standard Model also allows for processes that produce two Higgs bosons in the final state, known as Higgs pair production or di-Higgs production. The two main production mechanisms are shown in

figure 1.5.

**Figure 1.5:** The two leading diagrams for Standard Model di-Higgs production at the LHC: (a) box diagram, (b) Higgs self coupling

The two diagrams in figure 1.5 interfere destructively with one another, resulting in a low overall cross section for di-Higgs production at the LHC. Nevertheless, Higgs pair production is quite interesting to study because it gives direct access to the  $\lambda$  parameter of the Higgs potential, also known as the Higgs self coupling. The diagram in figure 1.5(b) is sensitive to this coupling through the triple Higgs vertex.

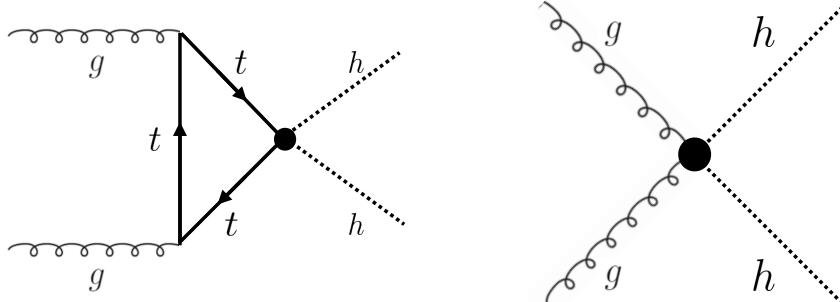

One can substitute the gluon fusion production of diagram 1.5(b) with any of the other production modes previously discussed. These other modes do not suffer from interference with the box diagram in figure 1.5(a) due to the presence of additional particles in the final state. They still have a lower cross section than the gluon fusion mode, however. The cross sections for di-Higgs production in the different modes, as well as their uncertainties, are shown in table 1.4 [11]. These are shown for  $\sqrt{s} = 14$  TeV as the higher center of mass energy is more sensitive to this process. Note that the scale of cross section quoted is now in fb rather than pb.

Production mode	$\sigma$ (fb)	Total uncert. (%)
Gluon fusion	33.89	+37.2 / - 27.8
Vector boson fusion	2.01	+7.6 / - 5.1
$W H H$	0.57	+3.7 / - 3.3
$Z H H$	0.42	+7.0 / - 5.5
$t\bar{t}H$	1.02	-

**Table 1.4:** Production cross sections for pair production of a 125 GeV Higgs boson at  $\sqrt{s} = 14$  TeV with total uncertainty [11]. The uncertainties include QCD scale and PDF variations as well as uncertainties on  $\alpha_S$ .

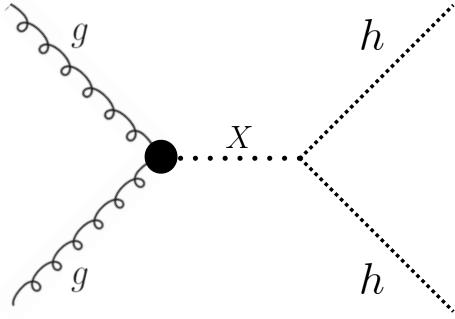

## 1.5 HIGGS PAIR PRODUCTION IN THEORIES BEYOND THE STANDARD MODEL

The Standard Model Higgs pair production cross section is rather small, and datasets on the scale of the full lifetime of the LHC will be required to obtain sensitive measurements of the Higgs self-coupling. However, the discovery of the Higgs also gives particle physicists a new tool that can be exploited in the search for new physics beyond the Standard Model. In particular, Higgs pair production is a promising channel in the search for new physics. The cross section for di-Higgs production can be altered through both resonant and non-resonant production of Higgs pairs. In non-resonant production, di-Higgs production vertices can arise from the presence of a new strong sector and additional colored particles[28–30]. Figure 1.6 shows examples of the types of vertices that can arise. In the resonant case, new heavy particle can decay to Higgs pairs. Such new particles can include heavy Higgs bosons arising in two Higgs doublet models (2HDM) or Higgs portal models as well as heavy gravitons in Randall-Sundrum theories[3, 5, 28, 31–35]. Figure 1.7 shows a generic diagram for a heavy resonance decaying to two Higgs bosons. In the 2HDM,  $X$  corresponds to the heavy CP-even scalar  $H$ . In the Randall-Sundrum model,  $X$  corresponds to a heavy spin-2 graviton  $G$ .

**Figure 1.6:** Diagrams with new vertices for non-resonant Higgs pair production arising in composite Higgs models

The next sections provide more detail on the phenomenology of resonant Higgs production in Randall-Sundrum and 2HDM models, as these models will later be tested in a dedicated search for resonant production of boosted Higgs pairs.

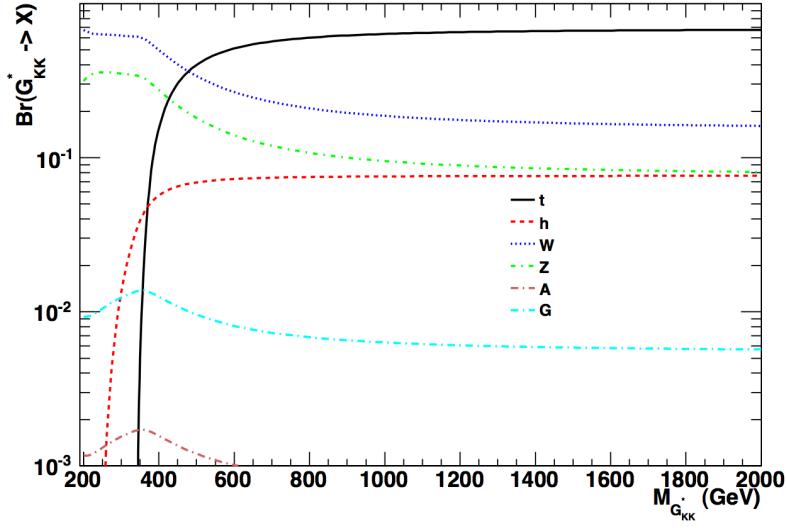

**Figure 1.7:** Generic Feynman diagram for resonant Higgs pair production in BSM theories

### 1.5.1 RANDALL-SUNDRUM GRAVITONS

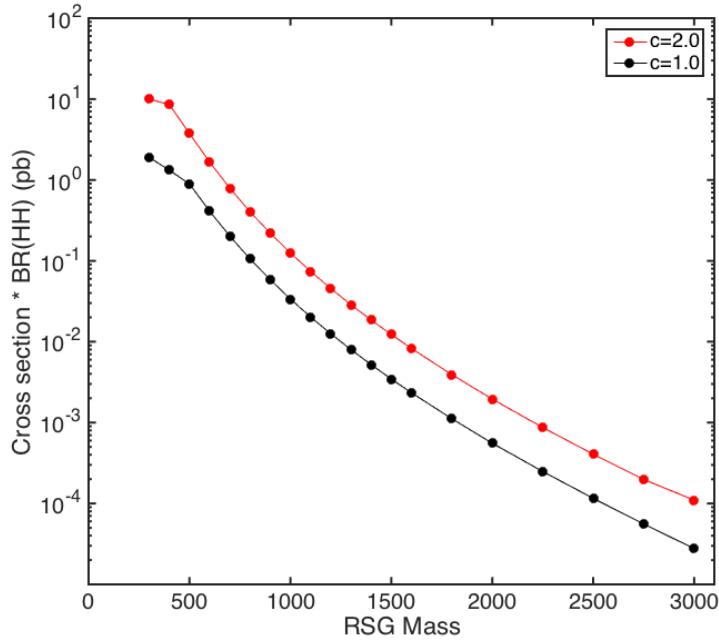

The Randall-Sundrum model is a proposed solution to the hierarchy problem that posits a five-dimensional warped spacetime that contains two branes: one where the force of gravity is very strong and a second brane at the TeV scale corresponding to the known Standard Model sector [31]. In the theory, the branes are weakly coupled and the graviton probability function drops exponentially going from the gravity brane to the SM brane, rendering gravity weak on the SM brane. The experimental consequence of this theory is a tower of widely spaced (in mass) Kaluza-Klein graviton resonances. In theories where the fermions are localized to the SM brane, production of gravitons from fermion pairs is suppressed and the primary mode of production is gluon fusion[3]. These gravitons have a substantial branching fraction to Higgs pairs, ranging from 6.43% for gravitons with a mass of 500 GeV to 7.66% at 3 TeV. Figure 1.8 shows the branching ratios of the spin-2 Randall Sundrum graviton (RSG) as a function of its mass. The predominant decays are to  $t\bar{t}$  above the mass threshold for that channel.

These models have two free parameters - the mass of the graviton and a curvature parameter  $k$ . Typically, rather than  $k$ , the theory is parameterized using  $c \equiv k/\bar{M}_{\text{pl}}$ , where  $\bar{M}_{\text{pl}}$  is the reduced Planck mass. The cross section for production of the RSG decreases as a function of mass and is strongly dependent on the gluon PDF. The increase in center of mass energy from 8 to 13 TeV in LHC Run 2 greatly increases the cross section at higher mass. Figure 1.9 shows the cross section as a function of graviton mass at  $\sqrt{s} = 13$  TeV for RSG models with  $c = 1.0$  and  $c = 2.0$ .

Another interesting feature of the theory is that the width of the graviton increases with both  $c$  and

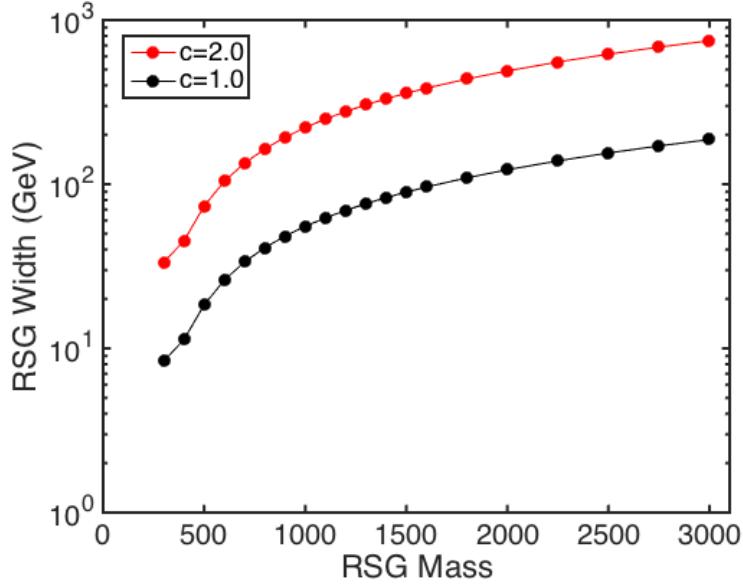

**Figure 1.8:** Branching ratios for a spin-2 Randall-Sundrum graviton as a function of mass computed in MadGraph with the CP3-Origins implementation [3, 4]

**Figure 1.9:**  $\sigma \times \text{BR}(HH)$  for RSG as a function of mass computed in MadGraph with the CP3-Origins implementation [3, 4]

$m_G$ . Figure 1.10 shows the graviton width for both  $c = 1.0$  and  $c = 2.0$  as a function of mass. In  $c = 1.0$ , the width starts at 8.365 GeV for a mass of 300 GeV and increases to 187.2 GeV at a mass of

3 TeV. Similarly, with  $c = 2.0$ , the width starts at 33.46 GeV for  $m_G = 300$  GeV and increases to 748.8 GeV at a mass of 3 TeV.

**Figure 1.10:** RSG width as a function of mass computed in MadGraph with the CP3-Origins implementation [3, 4]

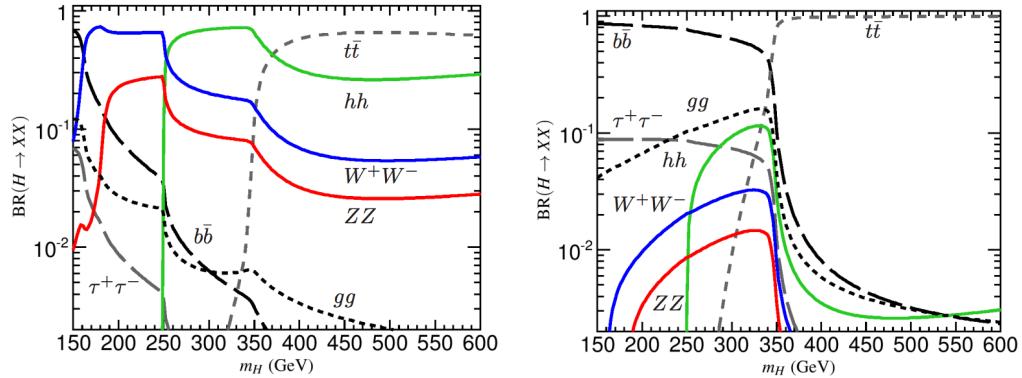

### 1.5.2 TWO HIGGS DOUBLET MODELS

In Two Higgs Doublet Models (2HDM), a second complex scalar doublet is added to SM [5, 33, 34]. In this case, all four degrees of freedom in the second doublet correspond to new particles, meaning that there are five total scalars from the two Higgs doublets -  $h$  (light CP-even Higgs),  $H$  (heavy CP-even Higgs),  $A$  (heavy CP-odd Higgs), and  $H^\pm$  (charged Higgs). The model is parameterized by two main parameters. The first,  $\tan \beta \equiv \frac{v_2}{v_1}$ , is the ratio of the vacuum expectation values of the two Higgs doublets (where  $v_1$  corresponds to the  $v$  in the SM Higgs model described above). The second parameter is  $\alpha$ , a mixing angle between the heavy and light Higgs fields. Models are also often parameterized with  $\cos(\beta - \alpha)$  rather than  $\alpha$  directly. The limit where  $\cos(\beta - \alpha) = 0$  is called the alignment limit, and it is in this limit that the light Higgs  $h$  has the same couplings as a Standard Model Higgs.

2HDM models are usually separated into two main types - Type I and Type II. In Type I models, the charged fermions only couple to the second Higgs doublet, leading to a fermiophobic light Higgs. In

Type II models, up-type quarks couple to the first doublet while down-type quarks couple to the second doublet. One specific realization of a Type II 2HDM is the Minimal Supersymmetric Standard Model (MSSM).

Resonant di-Higgs production in this model can proceed through decays of the heavy CP-even Higgs  $H \rightarrow hh$ . The branching ratio for  $H \rightarrow hh$  depends on the model type as well as the values of  $\tan \beta$  and  $\cos \beta - \alpha$ . Figure 1.11 shows the branching ratios as a function of the mass of the heavy scalar  $H$  for both Type I and Type II models. Depending on the type of model  $hh$  can be a substantial fraction of the decays of  $H$ .

**Figure 1.11:** Branching ratios for heavy Higgs  $H$  in Type I (left) and Type II (right) 2HDM models with  $\tan \beta = 1.5$  and  $\cos(\beta - \alpha) = 0.1(0.01)$  for Type I (Type II). [5]

## 1.6 CONCLUSION

Studying the Higgs sector is essential for understanding the details of how mass arises in the Standard Model and how the electroweak symmetry is broken. The discovery of the Higgs boson also opens the door for its use as a tool to search for new physics, and Higgs pair production is an ideal candidate for this study. Even if no BSM physics is found in Higgs pair production, searches for Higgs pairs will put constraints on the Higgs self coupling and thus further knowledge of the Standard Model and the details of the Higgs potential.

## The ATLAS detector and the Large Hadron Collider

This chapter presents an overview of the experimental systems used to conduct the measurements presented in this thesis. First, a brief overview of the accelerator, the Large Hadron Collider, will be given. In this section, the accelerator conditions relevant to data-taking are presented as well. Next, an overview of the ATLAS experiment is given. The basics of each sub-detector's role are summarized, as well as the details of the datasets accumulated. Then, a brief interlude on the ATLAS Muon New Small Wheel upgrade is presented. While this new detector does not have a direct impact on any of the datasets taken so far, it will have an impact on future analyses and the work done on it is briefly summarized here. Finally, an overview of object reconstruction in ATLAS is given. While the details of all of the algorithms will not be presented in detail, aspects of the reconstruction performance such as object resolutions are shown as these are relevant to the two studies presented later in this thesis.

## 2.1 THE LARGE HADRON COLLIDER

The Large Hadron Collider (LHC) is a proton-proton collider at the CERN laboratory in Geneva, Switzerland[36]. It is designed for a maximum collision center of mass energy of  $\sqrt{s} = 14 \text{ TeV}$  and has a circumference of 26.7 kilometers. Four main experiments are located at the interaction points (IP) of the accelerator: ATLAS (A Toroidal LHC ApparatuS), CMS (the Compact Muon Solenoid), ALICE (A Large Ion Collider Experiment), and LHCb [37–40]. The studies performed in this thesis were all completed with the ATLAS detector.

Figure 2.1 shows a schematic of the LHC ring and the various experiments.

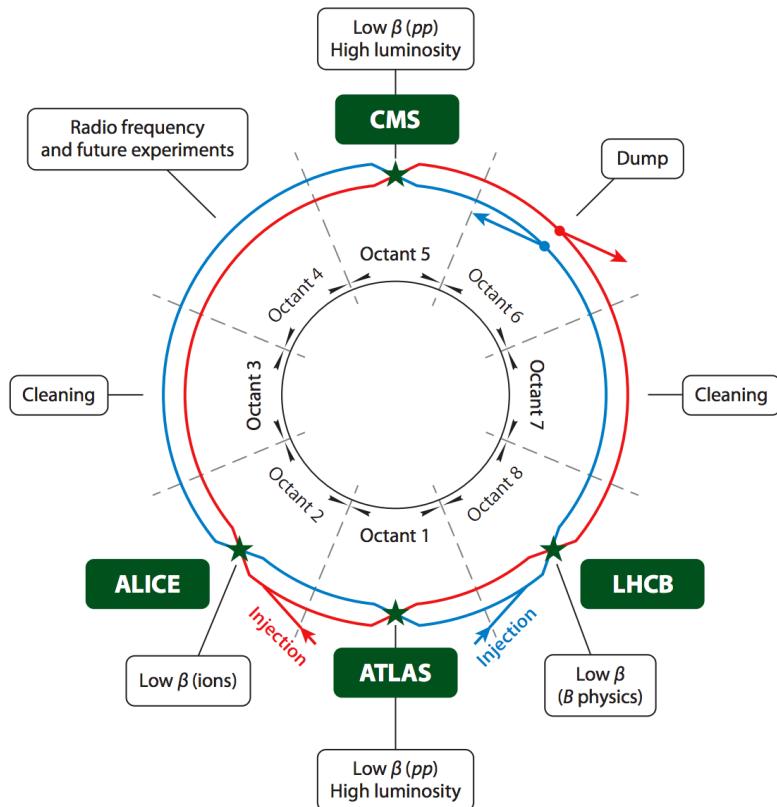

Figure 2.1: A schematic view of the LHC ring [6]

One of the most interesting features of the LHC is in its magnet design. Because the tunnel does not have room for separate superconducting magnets for each of the beam pipes, the LHC employs a twin-bore magnet design. Each magnet must hold an 8.3 Tesla magnetic field in order to bend the proton

beams at  $\sqrt{s} = 14$  TeV. The superconducting magnets are cooled to a temperature of 1.9 Kelvin with superfluid helium.

### 2.1.1 INSTANTANEOUS LUMINOSITY

The rate of physics events expected from the accelerator is dependent on the instantaneous luminosity of the machine and the cross section of the physics process,  $R_{\text{events}} = L\sigma$ . Here,  $R_{\text{events}}$  is the number of events per second,  $L$  is the instantaneous luminosity of the machine, and  $\sigma$  is the cross section for the physics process being measured. The instantaneous luminosity of the LHC is determined by numerous factors related to machine conditions. Equation 2.1 gives the equation for instantaneous luminosity of Gaussian beam profile [6].

$$L = \frac{N_b^2 n_b f_{\text{rev}} \gamma_r}{4\pi \epsilon_n \beta^*} F \quad (2.1)$$

The LHC collides protons in bunches, and in the above equation  $N_b$  is the number of protons per bunch while  $n_b$  is the number of bunches per beam. Nominally, the LHC can hold up to 2808 proton bunches.  $f_{\text{rev}}$  is the revolution frequency.  $\epsilon_n$  is the normalized transverse beam emittance, a measurement of the average spread of the particles position-momentum space which has the dimension of length.  $\beta^*$  is the value of the *beta* function for the beam at the interaction point. It relates the emittance to the Gaussian width of the beam with  $\sigma_{\text{beam}} = \sqrt{\epsilon \cdot \beta}$ .  $F$  is a reduction factor that corrects for the fact that the beams are colliding at an angle at the IP.

Another way of writing the instantaneous luminosity is shown in equation 2.2. In this case, the instantaneous luminosity is written as the ratio of the rate of inelastic collisions with the inelastic cross section[41].

$$L = \frac{R_{\text{inel}}}{\sigma_{\text{inel}}} = \frac{\mu n_b f_{\text{rev}}}{\sigma_{\text{inel}}} \quad (2.2)$$

In this case,  $\mu$  is the average number of interactions per bunch crossing in the accelerator.  $\mu$  is a useful parameter for characterizing the amount of activity recorded in an experiment. As the instantaneous

luminosity and thus  $\mu$  increase, there are more interactions per bunch crossing and more activity in the detector. This is often characterized with  $\langle \mu \rangle$ , the measured per bunch crossing  $\mu$  value averaged over all bunch crossings. The interactions inside each bunch crossing that are not the main physics process of interest are often referred to as “pileup” interactions, and  $\langle \mu \rangle$  is a measurement of the level of pileup in the detector.

### 2.1.2 EVOLUTION OF MACHINE CONDITIONS

This thesis uses datasets taken at three different center of mass energies:  $\sqrt{s} = 7$  TeV data taken in the year 2011,  $\sqrt{s} = 8$  TeV data taken in the year 2012, and  $\sqrt{s} = 13$  TeV dataa taken in the year 2015. In addition to increasing center of mass energy, the instananeous luminosity and parameters that determine it were evolving. Table 2.1 summarizes that machine conditions in each of these datasets.

	2011	2012	2015	Design
$\sqrt{s}$ [ TeV]	7	8	13	14
Number of bunches	1380	1380	1825	2808
Max. protons per bunch	$1.45 \times 10^{11}$	$1.7 \times 10^{11}$		$1.15 \times 10^{11}$
Bunch spacing [ns]	50	50	25	25
Max. instantaneous luminosity [ $\text{cm}^{-2}\text{s}^{-1}$ ]	$3.7 \times 10^{33}$	$7.7 \times 10^{33}$	$5 \times 10^{33}$	$10^{34}$
$\beta^*$ [m]	1.0	0.6	0.8	0.55
$\langle \mu \rangle$	11.6	20.7	13.7	-

## $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$ Analysis Strategy

### 3.1 INTRODUCTION

This chapter presents an overview of the strategy for searching for a Higgs boson in the  $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$  decay topology. Its purpose is to define in broad terms how the search and measurement are undertaken, before going into details on the specific sub-categories within the larger analysis. First, the properties of the Higgs signal are discussed and the associated backgrounds are presented. Next, the observables used to enhance the signal to background ratio are defined. Finally, the parameters of interest in the search and measurement will be shown, along with a brief overview of the statistical treatment of the final Higgs candidates.

Following this chapter, the results of three different studies within the  $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$  channel are shown. Chapter 4 presents a search for Higgs boson production in gluon fusion mode and the role of the  $H \rightarrow WW^*$  channel in its discovery. Chapter 5 shows the search and first observation in ATLAS of the Vector Boson Fusion (VBF) production mode of the Higgs in the  $H \rightarrow WW^*$  decay channel.

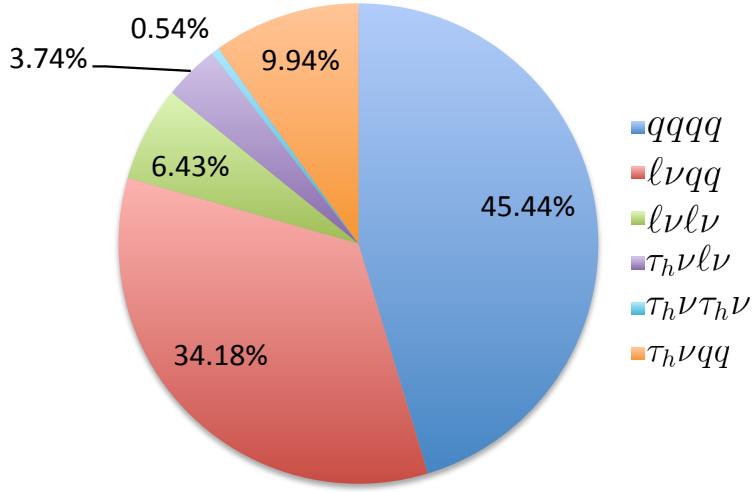

Finally, chapter 6 shows the combined Run 1  $H \rightarrow WW^*$  results for the measurement of the Higgs cross section and relative coupling strengths to other SM particles.

### 3.2 THE $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$ SIGNAL IN ATLAS

The signal studied in this and subsequent chapters is the Higgs boson in the  $WW^*$  final state, where each  $W$  boson subsequently decays into a charged lepton and a neutrino. In its simplest decay path, the final state consists of two neutrinos and two charged leptons, each of which can be either an electron or a muon. If one or both of the  $W$ s decay to  $\tau$  leptons, only leptonic decays of the  $\tau$  are considered. This decay path produces additional neutrinos in the final state but still gives two charged leptons as before. Neutrinos are not detected in ATLAS, so the final state ultimately consists of two reconstructed leptons and missing transverse momentum (denoted as  $E_T^{\text{miss}}$ ). Final states where both of the charged leptons are electrons or muons are referred to as the “same flavor” ( $ee/\mu\mu$ ) final states, while those with one electron and one muon are referred to as “different flavor” ( $e\mu$  or  $\mu e$ ).

While the basic final state consists of two leptons and  $E_T^{\text{miss}}$ , there can be additional objects depending on the production mode of the Higgs. As described in detail in Chapter 1, if the Higgs is produced via vector boson fusion production, there will be two additional forward jets in the event. Even in gluon fusion, one or more jets can be produced through initial state radiation from the incoming gluons. Because of the varying background composition as a function of jet multiplicity, each bin in this variable has its own dedicated requirements applied in the search and measurement. The  $n_j = 0$  and  $n_j = 1$  bins are dedicated to gluon fusion production, while the  $n_j \geq 2$  bin has separate dedicated searches for ggF and VBF production.

Figure 3.1 shows the relative branching fractions for the  $H \rightarrow WW^*$  process, calculated from the Particle Data Group values for the  $W$  and  $\tau$  branching ratios[?]. The largest branching ratio is both  $W$  bosons decaying to quark pairs at 45.44%. The next largest is one  $W$  decaying leptonically and the other decaying to quarks, a branching ratio of 34.18%. In all cases,  $\ell$  denotes either an electron or muon, and the leptonic branching ratios of the  $\tau$  are included. For example, the  $\ell\nu qq$  final state includes one  $W$  decaying to  $e\nu$ ,  $\mu\nu$ , or  $\tau\nu$ . In the case of the  $W \rightarrow \tau\nu$  decay, the  $\tau$  lepton then decays to an electron or

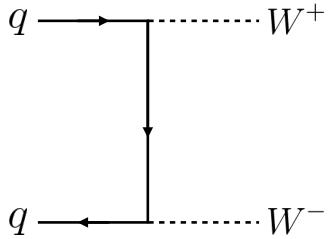

**Figure 3.1:** Branching ratios for a  $WW$  system.  $q$  refers to quarks.  $\ell$  can be either an electron or muon, and the leptonic branching ratios of the  $\tau$  are included. For example, the  $\ell\nu qq$  final state includes one  $W$  decaying to  $e\nu$ ,  $\mu\nu$ , or  $\tau\nu$ .  $\tau_h$  refer to hadronic decays of the  $\tau$ .

muon via  $\tau \rightarrow \nu_\tau \ell \nu_\ell$ . Final states with a  $\tau_h$  refer to hadronic decays of the  $\tau$ . The branching ratio to the  $\ell\nu\ell\nu$  final state is 6.43%.

While the  $\ell\nu\ell\nu$  final state is not a large fraction of the branching ratio, there are significant advantages in this channel. First, both the  $qqqq$  and  $\ell\nu qq$  channels suffer from a large QCD multijet background, which is often difficult to model. Second, events in the the  $\ell\nu\ell\nu$  channel in data can be triggered more efficiently due to the presence of two leptons.

### 3.3 BACKGROUND PROCESSES

Many processes from the Standard Model can also produce a final state with two leptons and missing transverse momentum . This section lists the dominant backgrounds to Higgs production. It gives general descriptions of how the backgrounds mimic Higgs production and how they can be reduced. Table 3.1 summarizes the different processes.

**Figure 3.2:** Feynman diagram for Standard Model WW production

### 3.3.1 STANDARD MODEL WW PRODUCTION

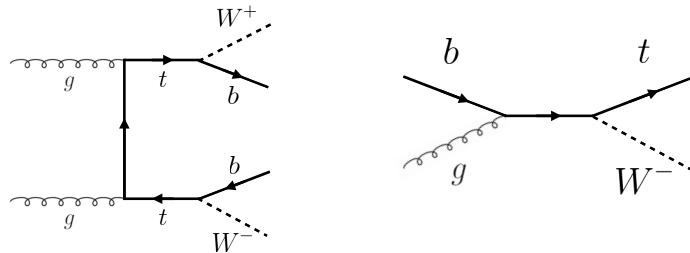

Non-resonant Standard Model diboson production, as shown in figure 3.2, is an irreducible background to Higgs boson production in the WW final state. It produces the same exact final state objects, namely leptonically decaying W bosons. There are no additional objects in the final state that allow for background reduction. Therefore the analysis solely relies on the correlations between the leptons to reduce this background.

### 3.3.2 TOP QUARK PRODUCTION

Production of top quarks, either in pairs ( $t\bar{t}$  production) or singly (e.g.  $Wt$  production), can also mimic Higgs production. Because top quarks decay via  $t \rightarrow Wb$ , top pair production can produce a final state with two W bosons that then decay leptonically. In this case, however, there are two additional jets from the bottom quarks in the final state. This allows the analysis to veto on the presence of jets identified as originating from a  $b$  in order to reduce the size of the background.

Single top production can occur via  $s$ -channel,  $t$ -channel, or associated production ( $Wt$ ). The mode which most closely resembles the Higgs final state is  $Wt$ . In this case, there are two real W bosons produced, as with  $t\bar{t}$ . However, the decay of the single top quark will still also produce one  $b$ -jet, meaning a  $b$  veto will reduce this background as well.

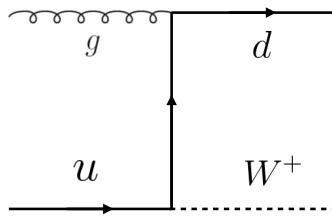

Figure 3.3 shows the Feynman diagrams for  $t\bar{t}$  and  $Wt$  production.

**Figure 3.3:** Feynman diagrams for top pair production (left) and  $Wt$  production (right)

### 3.3.3 $W$ +JETS BACKGROUND

Single  $W$  boson production, in association with jets, is a unique background. The other background considered so far have all included real leptons in the final state. In this case, however, only one real lepton from the decay of a  $W$  exists in the final state. The second reconstructed lepton can arise from two different cases. First, the lepton may truly be an algorithm “fake”, or a jet misidentified as a lepton by either the electron or muon reconstruction algorithms. Second, the lepton may be a real lepton but coming from semi-leptonic decays of particles inside the shower of the jet. This background can be reduced by requiring that the reconstructed lepton have little activity surrounding it in the calorimeter (also known as an “isolated” lepton). Figure 3.4 shows the Feynman diagram for  $W$ +jets production.

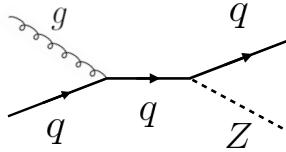

**Figure 3.4:** An example Feynman diagram of  $W$ +jets production

### 3.3.4 $Z/\gamma^*$ +JETS BACKGROUND

Production of a  $Z/\gamma^*$  in association with jets (also known as Drell-Yan) is also a background to Higgs production. In particular, the same flavor final states have a large  $Z$ +jets background, as the  $Z$  decays into two leptons of the same flavor. (This background also enters the different flavor final state through

the leptonic decays of  $Z \rightarrow \tau\tau$ ). Figure 3.5 shows the production of a  $Z$  in association with one jet. Because there are no neutrinos in this final state, variables like  $E_T^{\text{miss}}$  can be used to reduce the background.

**Figure 3.5:** An example Feynman diagram of  $Z + \text{jets}$  production

### 3.3.5 OTHER (SUBDOMINANT) BACKGROUNDS

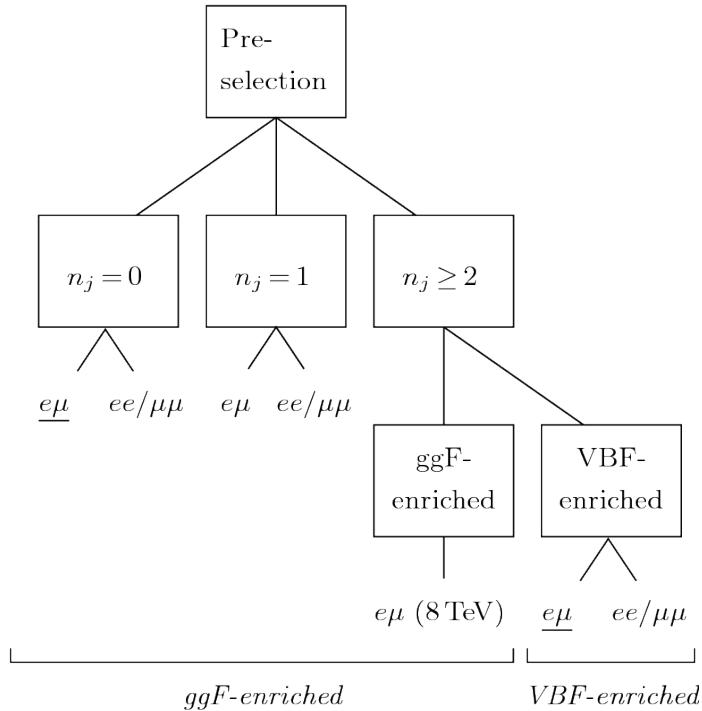

There are additional processes which contribute to the background composition but are not produced as frequently as those listed already. The first of these are referred to as  $VV$  or “Other diboson” processes and include multiple Standard Model diboson processes, including  $WZ$ ,  $ZZ$ ,  $W\gamma$ ,  $W\gamma^*$ , and  $Z\gamma$  production. Additionally, there is background from QCD multijet production, where two jets are misidentified as leptons.

Category	Process	Description
SM $WW$	$WW \rightarrow \ell\nu\ell\nu$	Real leptons and neutrinos
Top quark production	$t\bar{t} \rightarrow WbWb \rightarrow \ell\nu b\bar{b}\nu\bar{b}$ $tW \rightarrow WbW \rightarrow \ell\nu\ell\nu b$ $t\bar{b}, t\bar{q}\bar{b}$	Real leptons, untagged $b$ s Real leptons, untagged $b$ Untagged $b$ , jet misidentified as lepton
Drell-Yan	$Z/\gamma^* \rightarrow ee, \mu\mu$ $Z/\gamma^* \rightarrow \tau\tau \rightarrow \ell\nu\ell\nu\bar{\nu}$	“Fake” $E_T^{\text{miss}}$ Real leptons and neutrinos
Other dibosons	$ZZ \rightarrow \ell\ell\nu\nu$ $W\gamma^*, WZ \rightarrow \ell\nu\ell\ell, ZZ \rightarrow \ell\ell\ell\ell$ $W\gamma, Z\gamma$	Real leptons and neutrinos Unreconstructed leptons $\gamma$ reconstructed as $e$ , unreconstructed lepton
$W + \text{jets}$	$Wj \rightarrow \ell\nu j$	Jet reconstructed as lepton
QCD multijet	$jj$	Jets reconstructed as leptons

**Table 3.1:** A summary of backgrounds to the  $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$  signal

### 3.4 SHARED SIGNAL REGION SELECTION REQUIREMENTS

As presented in section 3.2, there are many different combinations of objects that can define a  $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$  final state. The multiplicity of jets and the flavor combinations of the leptons both lead to many potential signal regions. Additionally, signal regions can be optimized separately to be sensitive to the distinct production modes of the Higgs. Gluon fusion, vector boson fusion, and associated production of a Higgs all lead to unique final state topologies. Figure 3.6 delineates the different signal regions used in the gluon fusion and vector boson fusion  $H \rightarrow WW^*$  analyses. While there are different optimizations possible in each signal region, there are also some commonly shared selections that will be described here.

**Figure 3.6:** An illustration of the unique analysis signal regions[7]

#### 3.4.1 EVENT PRE-SELECTION

Before being sorted into the distinct signal regions, basic requirements are applied on the reconstructed objects in the event to select Higgs-like event candidates. First, two oppositely charged leptons are re-

quired.

Once the leptons are selected, the last requirement for event pre-selection is the presence of neutrinos. As neutrinos cannot be detected directly in ATLAS,  $E_T^{\text{miss}}$  can be used as a proxy for the combined neutrino momentum in the transverse plane. In general, it is expected that the signal should have a harder  $E_T^{\text{miss}}$  spectrum than backgrounds, especially if those backgrounds did not contain neutrinos. One additional consideration when using  $E_T^{\text{miss}}$  is the fact that mis-measurements of objects in the detector can lead to imbalances in the transverse plane that are not due to real particles escaping the detector. One indicator that this is the case is that the  $E_T^{\text{miss}}$  vector in the transverse plane will be pointing in the same direction as the mis-measured object. Therefore, a new variable,  $E_{T,\text{rel}}^{\text{miss}}$ , is used in the pre-selection.  $E_{T,\text{rel}}^{\text{miss}}$  is defined in equation 3.1.

$$E_{T,\text{rel}}^{\text{miss}} = \begin{cases} E_T^{\text{miss}} \sin \Delta\phi_{\text{near}} & \text{if } \Delta\phi_{\text{near}} < \pi/2 \\ E_T^{\text{miss}} & \text{otherwise,} \end{cases} \quad (3.1)$$

If the closest object to the  $E_T^{\text{miss}}$  vector is within  $\pi/2$  radians in the transverse plane, the  $E_T^{\text{miss}}$  is projected away from this object. Otherwise, the normal  $E_T^{\text{miss}}$  vector is used. Figure 3.7 shows a graphical illustration of this concept.

Once both the lepton and  $E_T^{\text{miss}}$  pre-selections are made, the analysis can be divided into different regions according to jet multiplicity.

### 3.4.2 JET MULTIPLICITY

Jet multiplicity, denoted as  $n_j$ , is used to sub-divide the analysis into its distinct signal regions. The reason for this is twofold. First, different jet multiplicity bins will be more or less sensitive to different Higgs production modes. For example, the  $n_j \geq 2$  region is more sensitive to VBF production because of the two high momentum jets produced at matrix element level. For gluon fusion production to enter this bin, two initial state radiation jets must be emitted. Second, background composition varies greatly in different bins of  $n_j$ . Figure 3.8 shows the jet multiplicity in both the different flavor and same flavor regions. It also shows the background composition in the bins of  $n_b$ . There are a few clear trends from

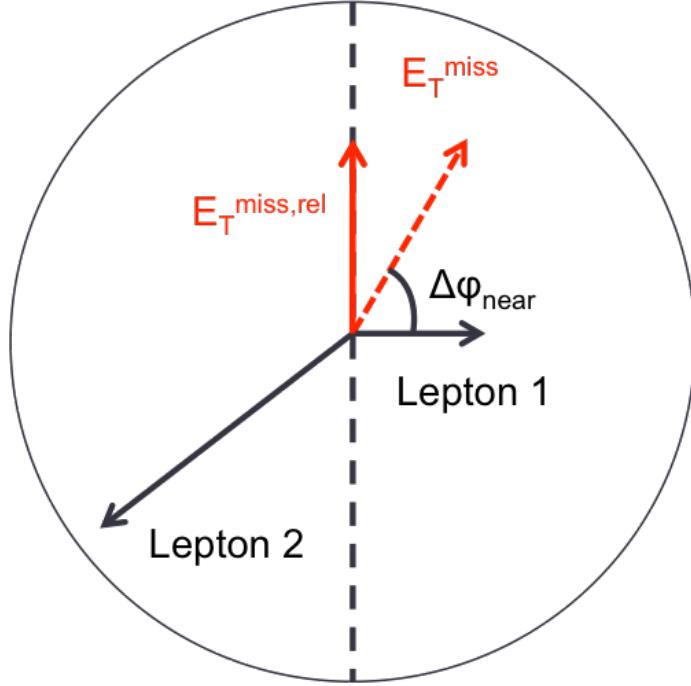

Figure 3.7: A graphical illustration of the  $E_{T,\text{rel}}^{\text{miss}}$  calculation

this distribution. The first is that the Drell-Yan background dominates in the same flavor channels for  $n_j \leq 1$ . Second, the top background becomes a clear contributor to the total background for  $n_j \geq 1$ . Lastly, the SM WW production dominates in the  $n_j = 0$  bin, as it is an irreducible background to  $H \rightarrow WW^*$  production. Because of these distinct features, each jet multiplicity bin is treated separately.

### 3.5 BACKGROUND REDUCTION IN SAME-FLAVOR FINAL STATES

As described in section 3.4.2, the background composition of the same flavor final states is unique to that of the different flavor states. In particular, Drell Yan processes play a much larger role because the  $Z/\gamma^*$  decays to same flavor leptons. Because real neutrinos are absent in the  $Z/\gamma^*$  decays to  $ee$  and  $\mu\mu$ , a requirement on  $E_T^{\text{miss}}$  should largely reduce the background. However, as this section will demonstrate, with increasing pileup conditions the resolution of the calorimeter-based  $E_T^{\text{miss}}$  degrades greatly. Therefore, two new variables for  $Z/\gamma^*$  background reduction are constructed and described in this section.

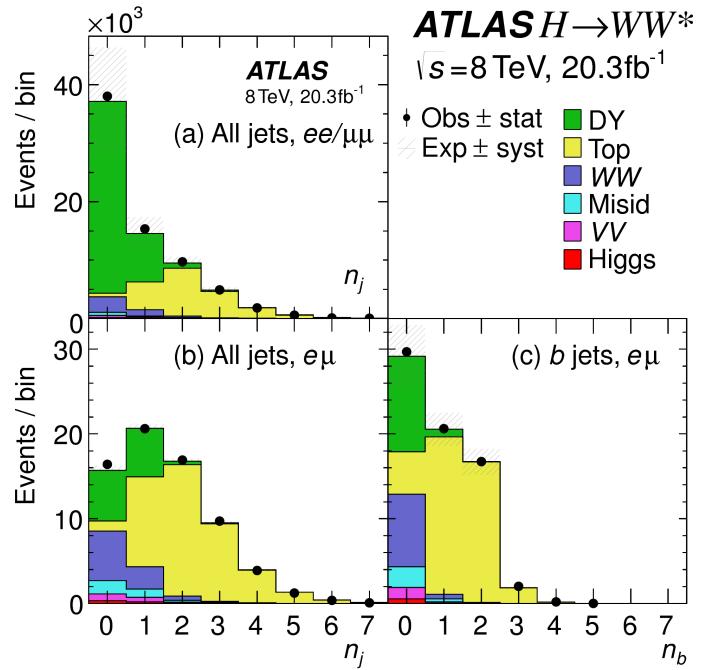

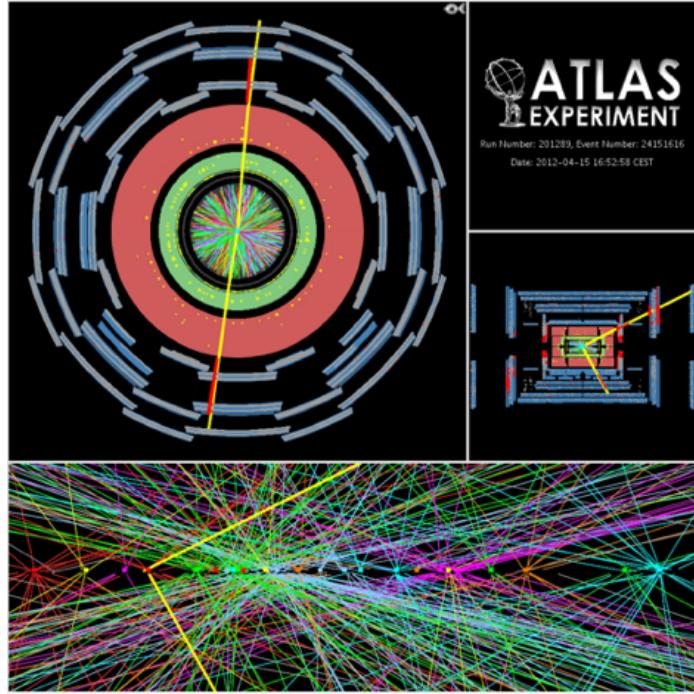

Figure 3.8: Predicted backgrounds (compared with data) as a function of  $n_j$  (a and b) and  $n_b$  (c)

### 3.5.1 PILEUP AND $E_T^{\text{miss}}$ RESOLUTION

Secondary interactions of protons in the colliding bunches of the LHC (known as pileup interactions, described in detail in Chapter 2) deposit energy into the ATLAS calorimeter on top of the energy that comes from the hard scatter process that is being searched for or analyzed. The calculation of  $E_T^{\text{miss}}$  is fundamentally Poissonian, as summing up all of the energy deposits in individual calorimeter cells or clusters is similar to a counting experiment. Thus, the energy resolution scales as  $\sqrt{E}$ , just as the error on a mean of  $N$  in a Poisson distribution is  $\sqrt{N}$ . As more energy is deposited in the calorimeter, the  $E_T^{\text{miss}}$  resolution degrades, meaning that the  $E_T^{\text{miss}}$  resolution is particularly sensitive to LHC instantaneous luminosity conditions.

Figure 3.9 shows an event display of a  $Z/\gamma^* + \text{jets}$  event candidate with the twenty-five reconstructed primary vertices. This display illustrates that while the interaction of interest only has tracks coming from the hardest primary vertex, all of the secondary interactions will deposit energy in the calorimeter as well.

Figure 3.10 shows the RMS of the  $E_T^{\text{miss}}$  distribution in  $Z \rightarrow \mu\mu$  events (where there are no real neu-

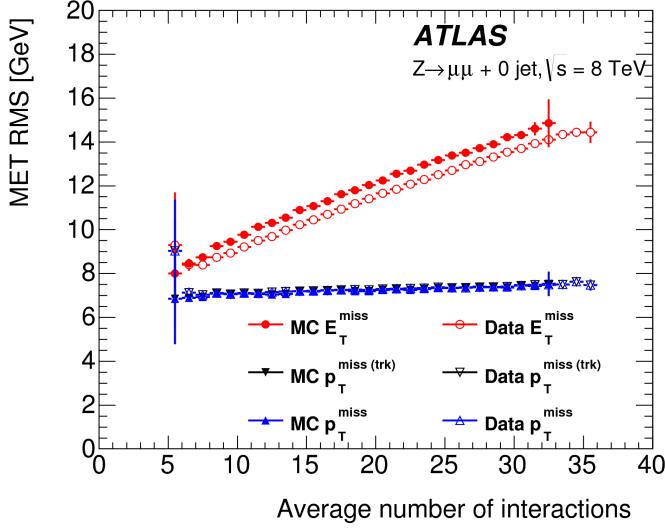

**Figure 3.9:** An event display of a  $Z/\gamma^*$  + jets event illustrating the effect of pileup interactions

trinos) as a function of the number of the average number of interactions. Under 2011 LHC conditions, this RMS was approximately 9 GeV, while under 2012 running conditions the resolution worsened to 12 GeV. This worsening dilutes the  $E_T^{\text{miss}}$  variable's ability to reduce the  $Z/\gamma^*$  background.

### 3.5.2 TRACK-BASED DEFINITIONS OF MISSING TRANSVERSE MOMENTUM

Because the increasing number of secondary proton-proton interactions degrades calorimeter-based  $E_T^{\text{miss}}$  resolution, a new variable using only contributions from the primary interaction vertex is necessary to further reduce the  $Z/\gamma^*$  background. While it is not possible to associate calorimeter energy deposits with a particular vertex, individual charged particle tracks in the Inner Detector are associated to unique vertices. Thus, two track-based definitions of missing transverse momentum , using only tracks coming from the primary vertex in the event, are used in the analysis. The simplest variable,  $p_T^{\text{miss}(\text{trk})}$ , is the vectorial sum of the  $p_T$  of all of the tracks from the primary vertex and the selected leptons (excluding the tracks associated with the selected leptons to avoid double counting). This is defined in equa-

**Figure 3.10:** The RMS of different missing transverse momentum definitions as a function of the average number of interactions per bunch crossing

tion 3.2.

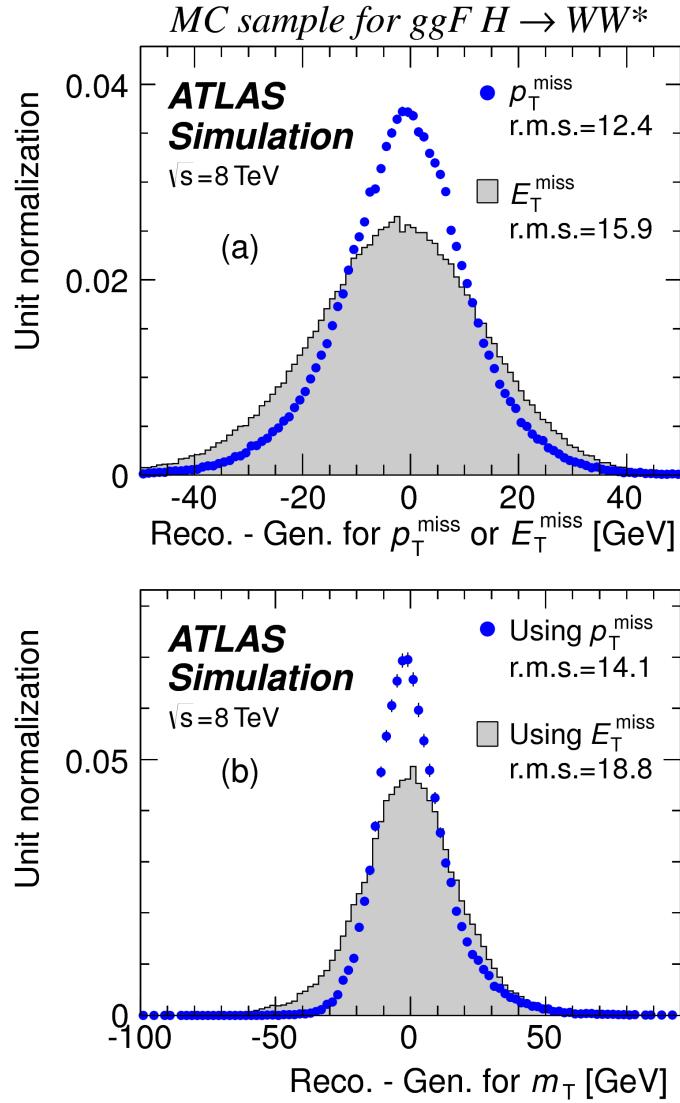

$$\mathbf{p}_T^{\text{miss}(\text{trk})} = - \left( \sum_{\text{selected leptons}} \mathbf{p}_T + \sum_{\text{other tracks}} \mathbf{p}_T \right), \quad (3.2)$$

In events with hard jets, a better resolution on the missing transverse momentum is obtained by including the calorimeter based measurement of the hard jets rather than the track based measurements. Thus, another variable,  $p_T^{\text{miss}}$ , is defined, using the nominal measurements of  $p_T$  for the selected leptons and jets and using tracks rather than calorimeter clusters for the soft component of the missing transverse momentum. This is defined in equation 3.3.

$$\mathbf{p}_T^{\text{miss}} = - \left( \sum_{\text{selected leptons}} \mathbf{p}_T + \sum_{\text{selected jets}} \mathbf{p}_T + \sum_{\text{other tracks}} \mathbf{p}_T \right), \quad (3.3)$$

Figure 3.10 illustrates that these two new variables accomplish their intended purpose. The resolution as a function of mean number of interactions for both  $p_T^{\text{miss}(\text{trk})}$  and  $p_T^{\text{miss}}$  is much flatter compared to the dependence for  $E_T^{\text{miss}}$ .

Figure 3.11a shows the difference between the true and reconstructed values of missing transverse mo-

**Figure 3.11:** The difference between the true and reconstructed values of the missing transverse momentum (a) and  $m_T$  (b) in a gluon fusion signal sample

momentum using both the track-based  $p_T^{\text{miss}}$  and calorimeter based  $E_T^{\text{miss}}$ . The RMS of the distribution improves by 3.5 GeV when using  $p_T^{\text{miss}}$ .

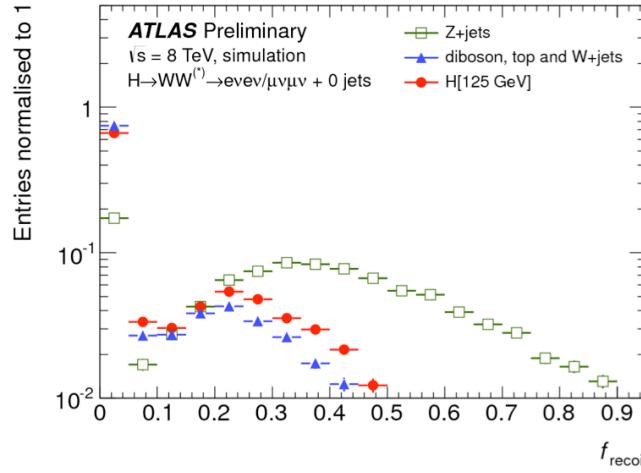

### 3.5.3 DISTINGUISHING $Z/\gamma^*$ +JETS AND $H \rightarrow WW^*$ TOPOLOGIES

The track-based definitions of missing transverse momentum were constructed to mitigate degrading performance as a function of pileup. However, an additional variable can be constructed to exploit kine-

matic and topological differences between the  $Z/\gamma^*$  background and  $H \rightarrow WW^*$  signal. Because there are no real neutrinos in the final state (in the case of  $Z/\gamma^* \rightarrow ee, \mu\mu$  decays), the dilepton system of a  $Z/\gamma^*$  will be balanced with the jets produced in the hard scatter. A new variable,  $f_{\text{recoil}}$ , is constructed to estimate the balance between the dilepton system and the jets in the quadrant opposite the dilepton vector in the transverse plane. It is defined in equation 3.4. The numerator of  $f_{\text{recoil}}$  is the magnitude of the vectorial sum of the  $p_T$  of jets in the quadrant opposite the dilepton system, weighted by each jet's Jet Vertex Fraction (JVF, described in chapter 2). The denominator is the magnitude of the dilepton  $p_T$ .

$$f_{\text{recoil}} = \left| \sum_{\text{jets } j \text{ in } \wedge} \text{JVF}_j \cdot \mathbf{p}_T^j \right| / p_T^{\ell\ell}. \quad (3.4)$$

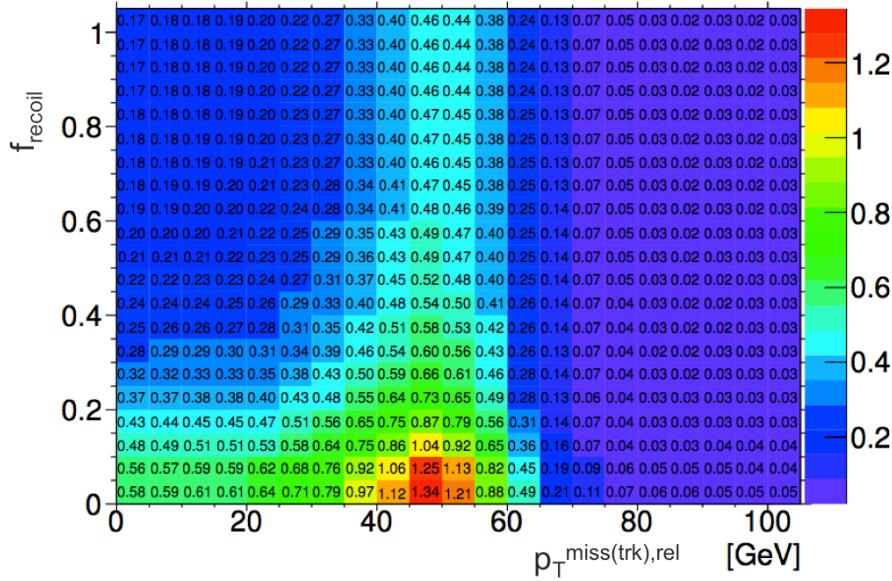

Figure 3.12 shows a shape comparison of the distribution of  $f_{\text{recoil}}$  in a simulated  $Z/\gamma^* + \text{jets}$  sample, a  $H \rightarrow WW^*$  signal sample, and other backgrounds that contain real neutrinos. The  $Z/\gamma^* + \text{jets}$  events tend to be more balanced between the dilepton system and recoiling jets, while the processes containing real neutrinos are less balanced in the transverse plane. Thus, a requirement on  $f_{\text{recoil}}$  will also reduce the  $Z/\gamma^* + \text{jets}$  background while maintaining a good signal efficiency.

**Figure 3.12:** Comparison of  $f_{\text{recoil}}$  distributions for  $Z/\gamma^* + \text{jets}$ ,  $H \rightarrow WW^*$ , and other backgrounds with real neutrinos.

### 3.5.4 OPTIMIZING BACKGROUND REDUCTION SELECTION REQUIREMENTS

The requirements on  $p_T^{\text{miss(trk)}}$  and  $f_{\text{recoil}}$  used to reduce the Z+jets background must be optimized to maximize their efficacy. Figure 3.13 shows an early attempt to optimize the combination of the two requirements in the gluon fusion zero jet bin. Each bin shows the expected signal significance if the  $p_{T,\text{rel}}^{\text{miss(trk)}}$  is required to be greater than the left edge of the bin and the  $f_{\text{recoil}}$  is required to be less than the top edge of the bin. The figure shows that the best signal significance comes from requiring low values of  $f_{\text{recoil}} (< 0.05)$  and  $p_{T,\text{rel}}^{\text{miss(trk)}}$  values greater than 45 GeV.

**Figure 3.13:** Signal significance as a function of required value for  $f_{\text{recoil}}$  and  $p_{T,\text{rel}}^{\text{miss(trk)}}$  in the ggF  $H \rightarrow WW^*$  with  $n_j = 0$

### 3.6 PARAMETERS OF INTEREST AND STATISTICAL TREATMENT

As with any search or measurement, there are particular parameters of the Higgs that the  $H \rightarrow WW^*$  analysis is interested in measuring. In this case, the parameters of interest are the mass of the Higgs boson and its production cross section. Because the  $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$  process does not have a closed final state, it is not possible to measure the full invariant mass of the particle that may have produced the final state. However, a proxy for the invariant mass using transverse plane information can be de-

fined. This is described in more detail in section 3.6.1. The second parameter of interest is the ratio of the measured cross section to that expected from the Standard Model Higgs, which is denoted a  $\mu$ . This is defined in equation 3.5.

$$\mu = \frac{\sigma}{\sigma_{\text{SM}}} \quad (3.5)$$

All of the likelihoods used in the statistical analysis of the final signal region events are paramaterized as a function of  $\mu$ .  $\mu$  is a natural variable for hypothesis testing, as  $\mu = 0$  corresponds to a background only hypothesis and  $\mu = 1$  corresponds exactly to a Standard Model Higgs.

### 3.6.1 TRANSVERSE MASS

Because the longitudinal information about the neutrinos is not attainable, the  $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$  analysis uses a mass variable, the transverse mass, that exploits information in the transverse plane as a proxy for the full invariant mass. The transverse mass is defined in equation 3.6.

$$m_T = \sqrt{(E_T^{\ell\ell} + p_T^{\text{miss}})^2 - |\vec{p}_T^{\ell\ell} + \vec{p}_T^{\text{miss}}|^2}, \quad (3.6)$$

Here the  $E_T^{\ell\ell}$  and  $p_T^{\ell\ell}$  are the transverse energy and momentum of the dilepton system, while  $p_T^{\text{miss}}$  is a proxy for the transverse momentum of the di-neutrino system. The track-based  $p_T^{\text{miss}}$  is used in the  $m_T$  rather than the calorimeter based  $E_T^{\text{miss}}$  because it has a better resolution on the true transverse mass. Figure 3.11b shows the improvement in the RMS of the difference between the true and reconstructed transverse mass in a ggF signal sample. The RMS improves by 4.7 GeV using  $p_T^{\text{miss}}$  in the  $m_T$  calculation.

### 3.6.2 STATISTICAL TREATMENT<sup>\*</sup>

#### LIKELIHOOD FUNCTION

The statistical analysis of final event candidates is framed as a hypothesis test, where the null hypothesis is background-only (no Standard Model Higgs). The first step in the analysis is to form a likelihood function for the data. In its simplest form, this likelihood is the probability of observing the number of events seen in the final signal region given knowledge of the signal strength. Because observation of events is fundamentally a Poisson counting experiment, this simple likelihood can be expressed as a Poisson probability of observing  $N$  events given a total number of predicted signal and background events. This basic likelihood is shown in equation 3.7.

$$\mathcal{L}(\mu) = P(N|\mu S + B) \quad (3.7)$$

Here,  $P$  is the Poisson probability density function,  $N$  is the total number of observed events,  $\mu$  is the signal strength,  $S$  is the predicted number of signal events, and  $B$  is the predicted number of background events.

In particle physics, certain background estimates are commonly normalized in so-called “control” regions and those predictions are scaled by the same normalization factor in the signal region. This leads to a slightly more complicated likelihood, which is a function of both the signal strength and the background normalization. This is shown in equation 3.8.

$$\mathcal{L}(\mu, \theta) = P(N|\mu S + \theta B) P(N_{\text{CR}}|\theta B_{\text{CR}}) \quad (3.8)$$

Here,  $\theta$  is a so-called “nuisance parameter”, a parameter that is not a primary parameter of interest but still enters the likelihood. The second Poisson term adds an extra term to the likelihood, enforcing the fact that the background normalization must be consistent with the number of observed events in data in the control region,  $N_{\text{CR}}$ .

So far, these two formulations of likelihoods have assumed a single signal region and do not take into

---

<sup>\*</sup>Many thanks to Aaron Armbruster, whose thesis[42] inspired parts of this section.

account any shape information of potential discriminating variables. The  $H \rightarrow WW^*$  analysis is divided into many different categories, and we can perform the same counting experiment described above in each individual category. As mentioned in section 3.6.1, the transverse mass is used as the primary discriminating variable in many of the  $H \rightarrow WW^*$  sub-analyses, so additionally we can perform the same counting experiment in each bin of the  $m_T$  distribution to incorporate some shape information. Thus, the total likelihood becomes a product over signal regions and bins of the  $m_T$  distribution. Finally, there are usually many backgrounds that are normalized in control regions, so the new formulation of the likelihood takes this into account as well by including a product over control regions in the second Poisson term. All of these modifications are shown in equation 3.9.

$$\mathcal{L}(\mu, \theta) = \prod_{\substack{\text{SRs } i \\ \text{bins } b}} P \left( N_{ib} \middle| \mu S_{ib} + \sum_{\text{bkg } k} \theta_k B_{kib} \right) \prod_{\text{CRs } l} P \left( N_l \middle| \sum_{\text{bkg } k} \theta_k B_{kl} \right) \quad (3.9)$$

The final step to get the full likelihood used in the analysis is to add nuisance parameters for the systematic uncertainties. In cases where the uncertainty does not affect the shape of  $m_T$  bin-by-bin, each systematic uncertainty  $\epsilon$  is allowed to affect the expected event yields through a linear response function of the nuisance parameter, namely  $\nu(\theta) = (1 + \epsilon)^\theta$ . If instead the uncertainty does affect the shape, the effect is instead parameterized by  $\nu_b(\theta) = 1 + \epsilon_b \theta$ . The value of the nuisance parameters for the systematic uncertainty are constrained with a Gaussian term that is added to the likelihood as well. This is of the form  $g(\delta|\theta) = e^{-(\delta-\theta)^2/2}/\sqrt{2\pi}$ , where  $\delta$  is the central value and  $\theta$  is a nuisance parameter. Finally, a last term is added to account for the statistical uncertainty in the Monte Carlo samples used, which adds an additional poisson term. The full likelihood used in the final statistical analysis is defined

in equation 3.10.

$$\begin{aligned} \mathcal{L}(\mu, \boldsymbol{\theta}) = & \prod_{\substack{\text{SRs i} \\ \text{bins b}}} P\left(N_{ib} \middle| \mu S_{ib} \cdot \prod_{\substack{\text{sig.} \\ r}} \nu_{br}(\theta_r) + \sum_{\text{bkg k}} \theta_k B_{kib} \cdot \prod_{\substack{\text{bkg.} \\ s}} \nu_{bs}(\theta_s)\right) \\ & \cdot \prod_{\text{CRs l}} P\left(N_l \middle| \sum_{\text{bkg k}} \theta_k B_{kl}\right) \\ & \cdot \prod_{\substack{\text{syst} \\ t}} g(\delta_t | \theta_t) \cdot \prod_{\text{bkg k}} P(\xi_k | \zeta_k \theta_k) \end{aligned} \quad (3.10)$$

In the fourth term of the equation, quantifying uncertainty due to finite Monte Carlo sample size,  $\xi$  represents the central value of the background prediction,  $\theta$  is the associated nuisance parameter,  $\zeta = (B/\delta B)^2$ , where  $\delta B$  is the statistical uncertainty of  $B$ .

The best fit value of the signal strength  $\mu$  is determined by finding the values of  $\mu$  and  $\boldsymbol{\theta}$  that maximize the likelihood, while setting  $\delta = 0$  and  $\xi = \zeta$ .

Once the likelihood is defined, a test statistic must be built for use in hypothesis testing.

## TEST STATISTIC

To distinguish whether the data match a background only or background and signal hypothesis, a test statistic must be used. The  $H \rightarrow WW^*$  analysis used the profile likelihood technique[43]. The first step in formulating this test statistic is to define the profile likelihood ratio, shown in equation 3.11.

$$\lambda(\mu) = \frac{\mathcal{L}(\mu, \hat{\theta}_\mu)}{\mathcal{L}(\hat{\mu}, \hat{\theta})} \quad (3.11)$$

Here  $\hat{\theta}_\mu$  is the value of  $\theta$  that maximizes the likelihood for the choice of  $\mu$  being tested. Additionally,  $\hat{\theta}$  and  $\hat{\mu}$  represent the values of  $\theta$  and  $\mu$  that gives the overall maximum value of the likelihood.

Once this is defined, a test statistic  $q_\mu$  is constructed. This is shown in equation 3.12.

$$q_\mu = -2 \ln \lambda(\mu) \quad (3.12)$$

A higher value of  $q_\mu$  means that the data are more incompatible with the hypothesized value of  $\mu$ , and  $q_0$  then corresponds to the value of the test statistic for the background only hypothesis. A  $p_0$  value is then defined to quantify the compatibility between the data and the null hypothesis. The  $p_0$  value is the probability of obtaining a value of  $q_0$  larger than the observed value, and this is shown in equation 3.13.

$$p_0 = \int_{q_0^{\text{obs}}}^{\infty} f(q_\mu | \mu = 0) dq_\mu \quad (3.13)$$

Here  $f(q_\mu)$  is the probability distribution function of the test statistic. Finally, the  $p_0$  value can be converted into a signal significance, using the formula in equation 3.14, or the one-sided tail of the Gaussian distribution.

$$Z_0 = \sqrt{2} \operatorname{erf}^{-1}(1 - 2p_0) \quad (3.14)$$

The threshold for discovery used in particle physics is  $Z_0 \geq 5$ , more commonly known as a value of  $5\sigma$ .

## The discovery of the Higgs boson and the role of the $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$ channel

### 4.1 INTRODUCTION

This chapter presents the results of the search for the Higgs boson in  $4.8 \text{ fb}^{-1}$  collected at  $\sqrt{s} = 7 \text{ TeV}$  and  $5.8 \text{ fb}^{-1}$  at  $\sqrt{s} = 8 \text{ TeV}$ . The results of three searches at  $\sqrt{s} = 8 \text{ TeV}$  in the  $H \rightarrow \gamma\gamma$ ,  $H \rightarrow ZZ \rightarrow 4\ell$ , and  $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$  channels are combined with results of searches at  $\sqrt{s} = 7 \text{ TeV}$  in the same search channels (as well as the  $H \rightarrow \tau\tau$  production and associated production searches for  $H \rightarrow b\bar{b}$ ). The results of this combination are a  $5.9\sigma$  detection of a new particle consistent with a Higgs boson. Rather than going into detail for all of the different Higgs decay searches, this chapter will discuss the three most sensitive channels and in particular give a comparison of the  $\gamma\gamma$  and  $4\ell$  channels to the  $\ell\nu\ell\nu$  channel. This chapter is a summary of results presented in the ATLAS Higgs discovery

publication[8].

## 4.2 DATA AND SIMULATION SAMPLES

The data sample used for the following results was taken in 2011 and 2012 at center of mass energies of 7 and 8 TeV, respectively, with  $4.8 \text{ fb}^{-1}$  collected at 7 TeV and  $5.8 \text{ fb}^{-1}$  collected at 8 TeV. Higgs production in the gluon fusion and vector boson fusion modes is modeled with **POWHEG** for the hard scattering event and **PYTHIA** for the showing and hadronization. Associated production of a Higgs with a vector boson or top quarks is modeled via **PYTHIA**.

Table 4.1 shows the Monte Carlo generators used for modeling the signal and background processes relevant for the three analyses to be discussed.

Process	Generator
ggF, VBF $H$	POWHEG + PYTHIA
$WH, ZH, t\bar{t}H$	PYTHIA
$W + \text{jets}, Z/\gamma^* + \text{jets}$	ALPGEN + HERWIG
$t\bar{t}, tW, tb$	MC@NLO + HERWIG
$tqb$	ACERMC + PYTHIA
$q\bar{q} \rightarrow WW$	MC@NLO + HERWIG
$gg \rightarrow WW$	GG2WW+ HERWIG
$q\bar{q} \rightarrow ZZ$	POWHEG + PYTHIA
$gg \rightarrow ZZ$	GG2ZZ+ HERWIG
$WZ$	MADGRAPH+ PYTHIA , HERWIG
$W\gamma + \text{jets}$	ALPGEN + HERWIG
$W\gamma^*$	MADGRAPH+ PYTHIA
$q\bar{q}/gg \rightarrow \gamma\gamma$	SHERPA

**Table 4.1:** Monte carlo generators used to model signal and background for the Higgs search[8].

## 4.3 $H \rightarrow \gamma\gamma$ SEARCH

The  $H \rightarrow \gamma\gamma$  search is in essence a search for a peaked excess above the falling SM diphoton mass spectrum, with  $m_{\gamma\gamma}$  as the ultimate discriminating variable. Events are selected by requiring two isolated photons, with the leading (sub-leading) photon required to have  $E_T > 40(30)$  GeV. In the 8 TeV data, the photons are required to pass cut-based identification criteria consistent with a photon in the electro-

magnetic calorimeter and little leakage in the hadronic calorimeter. The main challenges for this analysis are accurate mass reconstruction and background estimation. These are the issues that will be discussed in this section.

#### 4.3.1 DIPHOTON INVARIANT MASS RECONSTRUCTION

In order to accurately reconstruct the invariant mass of the di-photon system, both the energy and direction of the photons must be measured well. The  $\eta$  coordinate of the photons is calculated using the position of the primary vertex identified in the event as well as the entry points of the photons in the calorimeter. Therefore, the identification of the primary vertex of the hard interaction is particularly important, and is done using a likelihood which combines the flight direction of the photons, the beam position measurement, and the scalar sum of  $p_T^2$  for tracks at the primary vertex. This gives a resolution of 15 mm on the  $z$  position of the primary vertex (which improves to 6 mm for photons which convert to electron-positron pairs in the ID material).

In the inclusive sample, there are 35251 events observed in the 8 TeV sample and 23788 observed in the 7 TeV sample. The total expected number of events for a Higgs at 126.5 GeV is 110.5 at 8 TeV and 79.6 at 7 TeV. The full width at half maximum (FWHM) of the mass distribution at this mass is 3.9 GeV in the inclusive sample. The mass distribution is modeled with a crystal ball function for the core and a Gaussian for the tails, and the width of the core is 1.6 GeV in the inclusive sample. The events are additionally categorized based on the types of photons in the event, leading to ten distinct categories which have varying  $S/B$  and mass resolution. The best expected FWHM of 3.2 GeV comes from the category with unconverted photons at high  $p_{Tt}$  (the component of the diphoton  $p_T$  orthogonal to the axis defined by the vectorial difference of their momenta). The worst expected FWHM of 6.1 GeV comes from converted photons in the transition region of the calorimeter.

#### 4.3.2 BACKGROUND ESTIMATION

The background is modeled with a falling spectrum in  $m_{\gamma\gamma}$  that is parameterized by different functions depending on the category of the event. An exponential function of a second order polynomial is used

for the categories involving low  $p_{Tt}$  photons in the central region, as well as photon conversions in the transition region. A fourth order Bernstein polynomial is used the low  $p_{Tt}$  categories outside of the central region as well as the inclusive category. An exponential function is used for all other categories.

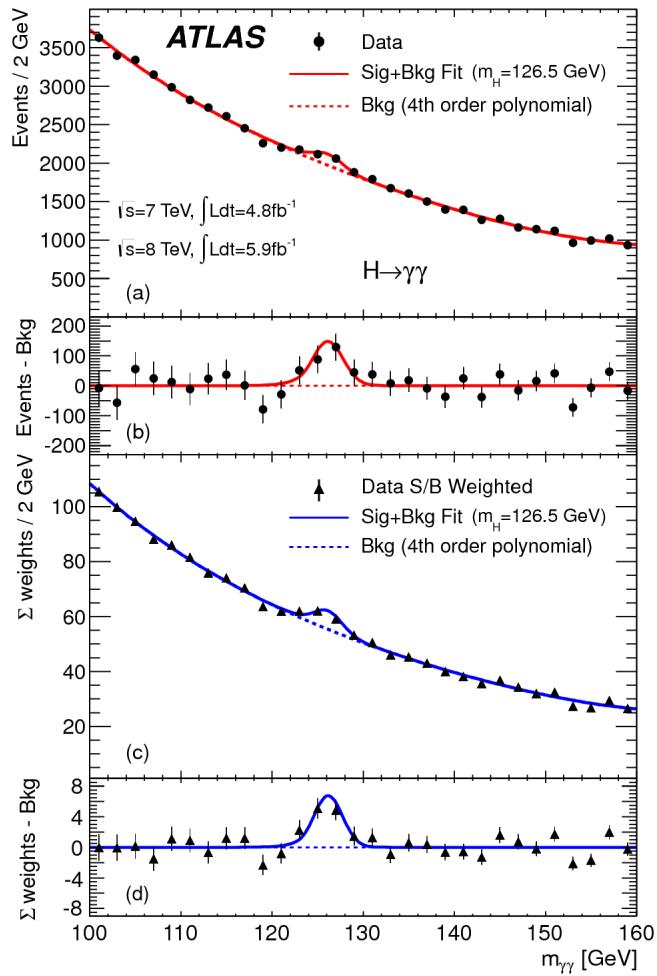

One important consideration when using such a background model is how much the model could be biased by a signal arising in the data. This level of potential bias from a signal is estimated using the mass spectrum of background plus signal from simulation (with the background shape in simulation validated using data-driven control regions). For this test, the signal shape is taken from simulation but the yield is left as a free parameter. The bias is then taken as the largest absolute yield coming from the likelihood fit. This potential bias is taken as a systematic uncertainty and amounts to  $\pm(0.3\text{-}6.8)$  events in the 8 TeV data sample.

#### 4.3.3 RESULTS

The resulting diphoton mass spectrum is shown in figure 4.1. The best fit mass value in the  $\gamma\gamma$  channel alone in the combined 7 and 8 TeV data is 126.5 GeV. The local significance at this point is  $4.5\sigma$ , with an expected significance of  $2.5\sigma$ . Therefore, the measured signal strength  $\mu$  is  $1.8 \pm 0.5$  in this channel.

#### 4.4 $H \rightarrow ZZ \rightarrow 4\ell$ SEARCH

The  $H \rightarrow ZZ \rightarrow 4\ell$  analysis searches for a Standard Model Higgs boson decaying to two  $Z$  bosons, each of which decays to a pair of same flavor, opposite charge isolated leptons. The ultimate discriminating variable is  $m_{4\ell}$ , or the invariant mass of the four selected leptons. The  $\ell$  denotes an  $e$  or  $\mu$  as with the  $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$  analysis. Electrons must have  $p_T > 7$  GeV and  $|\eta| < 2.47$ , while muons must have  $p_T > 6$  GeV and  $|\eta| < 2.7$ . There are then additional  $p_T$  cuts depending on the relative ranking of the lepton  $p_T$ , with the leading lepton required to have  $p_T > 20$  GeV, subleading lepton  $p_T > 15$  GeV, and third leading lepton  $p_T > 10$  GeV.

**Figure 4.1:** Diphoton mass spectrum in 7 and 8 TeV data. Panel a) shows the unweighted data distribution superimposed on the background fit, while panel c) shows the data where each event category is weighted by its signal to background ratio. Panels b) and d) show the respective distributions with background subtracted[8].

#### 4.4.1 LEPTON PAIR CONSTRUCTION

One of the difficult aspects of this channel is that there are multiple possible same flavor, opposite charge lepton pairs that can be produced out of the four selected leptons. The lepton pair whose mass is closest to  $m_Z$  is referred to as the leading pair and its mass is denoted as  $m_{12}$ , while the other lepton pair's mass is  $m_{34}$ . Events are required to have  $m_{12}$  consistent with a  $Z$  mass, or  $50 < m_{12} < 106$  GeV.  $m_{34}$  is required to be less than 115 GeV. The minimum requirement for  $m_{min}$  varies from 17.5 GeV at  $m_{4\ell} = 120$  GeV to 50 GeV at  $m_{4\ell} = 190$  GeV.

Four distinct signal regions are constructed depending on the flavors of the final state, additionally separated by the flavor of the leading lepton pair. These are referred to as  $4e$ ,  $2e2\mu$ ,  $2\mu2e$ ,  $4\mu$ .

Table 4.2 summarizes the mass resolutions and selection efficiencies for the four signal regions. The mass resolution at 125 GeV is dominated by experimental resolution, ranging from 1.7 GeV to 2.3 GeV.

Channel	Efficiency	Mass resolution
$4\mu$	36%	1.7 GeV
$2e2\mu$	22%	1.7 GeV
$2\mu2e$	22%	2.2 GeV
$4e$	20%	2.3 GeV

**Table 4.2:** A summary of selection efficiencies and expected resolutions for a 125 GeV Higgs in the  $H \rightarrow ZZ \rightarrow 4\ell$  channel[8].

#### 4.4.2 BACKGROUND ESTIMATION

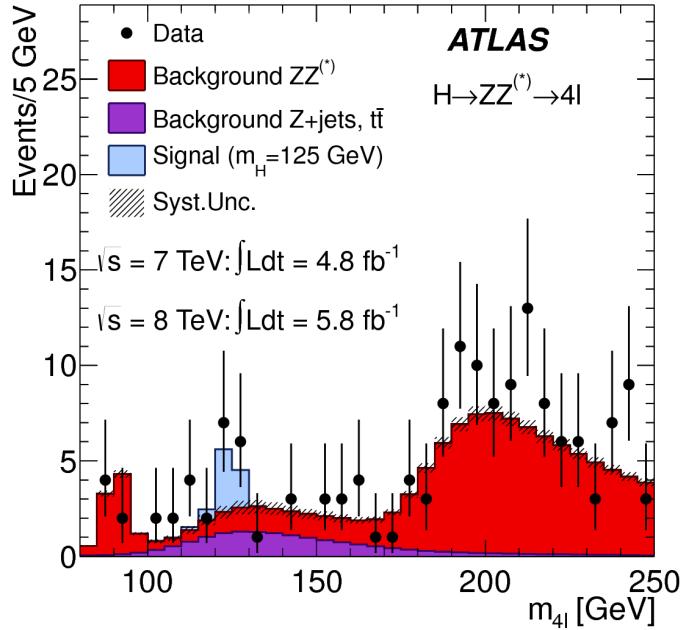

The main backgrounds in the  $H \rightarrow ZZ \rightarrow 4\ell$  search are continuum  $ZZ^*$  production,  $Z + \text{jets}$  production, and  $t\bar{t}$ . The  $m_{4\ell}$  distribution for background is estimated from simulation. The normalization of the SM  $ZZ^*$  background is also taken from MC simulation, while the  $Z + \text{jets}$  and  $t\bar{t}$  normalizations are taken from data-driven methods. The data-driven methods are separated into  $\ell\ell + \mu\mu$  and  $\ell\ell + ee$  methods.

In the  $\ell\ell + \mu\mu$  case, the control region is defined by relaxing the requirements on the  $\mu\mu$  pair to create a region enriched in background. The  $t\bar{t}$  and  $Z + \text{jets}$  backgrounds are then fit together from the leading mass distribution  $m_{12}$ . A similar method is used in the  $\ell\ell + ee$  case, but there is an additional sorting into categories based on identification criteria for electrons that come from heavy flavor decays or photon conversions.

#### 4.4.3 RESULTS

Figure 4.2 shows the  $m_{4\ell}$  spectrum measured in the 7 and 8 TeV datasets. The total number of events observed in the window between 120 and 130 GeV is 13, with 6 events in the  $4\mu$  channel, 2 events in the  $4e$  channel, and 5 events in the  $2e2\mu/2\mu2e$ . The best fit  $\mu$  value in the combined 7 and 8 TeV data

occurs at 125 GeV and is measured to be  $1.2 \pm 0.6$ . The observed significance at this mass is  $3.6\sigma$ , with an expected significance of  $2.7\sigma$ .

**Figure 4.2:** Four lepton invariant mass spectrum ( $m_{4\ell}$ ) in 7 and 8 TeV data compared to background estimate. A 125 GeV SM Higgs signal is shown in blue[8].

#### 4.5 $H \rightarrow WW \rightarrow e\nu\mu\nu$ SEARCH

The  $H \rightarrow WW \rightarrow e\nu\mu\nu$  search is unique compared to the  $ZZ$  and  $\gamma\gamma$  channels. The Higgs mass cannot be fully reconstructed due to the presence of neutrinos in the final state, so the transverse mass  $m_T$  is used as the final discriminating variable. Compared to the other channels, there are more backgrounds here as well, as discussed in chapter 3. The same flavor final states are excluded from this search due to high pileup in the 8 TeV dataset.

##### 4.5.1 EVENT SELECTION

The analysis requires two opposite charge isolated leptons, with the leading (sub-leading) lepton required to have  $p_T > 25(15)$  GeV. The events are separated into different signal regions depending on which

flavor of lepton is leading ( $e\mu$  for leading electron,  $\mu e$  for leading muon). Strict lepton quality cuts are applied to the sample to reduce backgrounds from fake leptons.

Jets are reconstructed with the anti- $k_T$  algorithm with a radius parameter  $R = 0.4$ . The jets are required to have  $p_T > 25 \text{ GeV}$  and  $|\text{eta}| < 4.5$ , with jets in the tracking volume required to have a jet vertex fraction of 0.5 and jets in the forward region required to have  $p_T > 30 \text{ GeV}$ . The analysis is separated into three different signal regions based on jet multiplicity:  $n_j = 0, 1, \geq 2$ .

To indicate the presence of neutrinos in the event, a requirement of  $E_{\text{T},\text{rel}}^{\text{miss}} > 25 \text{ GeV}$  is made. This requirement significantly reduces the QCD multijet and  $Z/\gamma^* + \text{jets}$  backgrounds.

Additional selections are applied to require the dilepton topology to correspond to that of a SM Higgs. The requirements are presented here - more detailed discussion on the motivation for each requirement is saved for Chapter 5. In all of the jet multiplicity channels, the dilepton system is required to have a small gap in azimuthal angle,  $\Delta\phi_{\ell\ell} < 1.8$ . Similarly, the  $m_{\ell\ell}$  is required to be less than 50 GeV in the lower jet multiplicity channels and less than 80 GeV in the  $n_j \geq 2$  channel. In the  $n_j = 0$  channel, the magnitude of the dilepton  $p_T$ ,  $p_T^{\ell\ell}$ , is required to be greater than 30 GeV.

In the higher jet multiplicity channels ( $n_j \geq 1$ ), the top background is a more important component and must be reduced. The total transverse momentum  $p_T^{\text{sum}}$  is thus required to be less than 30 GeV. Additionally, the di- $\tau$  invariant mass  $m_{\tau\tau}$  (dilepton mass computed under the assumption that the neutrinos from the  $\tau$  decay are emitted collinear to the charged leptons) is used to reject  $Z \rightarrow \tau\tau$  events by requiring  $|m_{\tau\tau} - m_Z| > 25 \text{ GeV}$ . These variables are also discussed in more detail in Chapter 5.

In the  $n_j \geq 2$  channel, requirements are made to isolate the VBF contribution to Higgs production. The kinematics of the two leading jets are used to make these requirements. In particular, the event must have  $\Delta y_{jj} > 3.8$  and  $m_{jj} > 500 \text{ GeV}$ , along with a veto on having any additional jets with rapidity between the two leading jets.

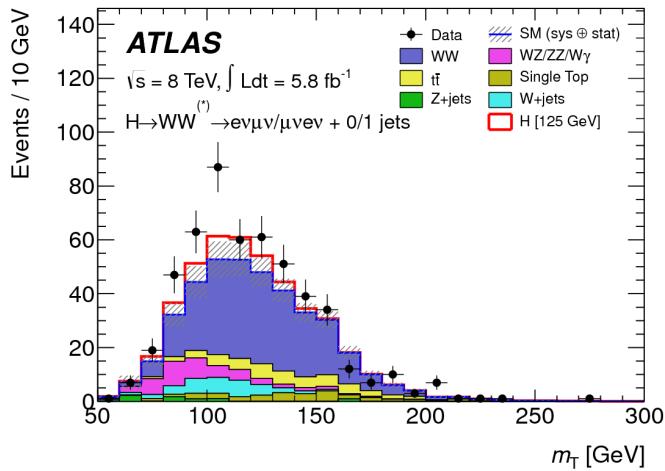

#### 4.5.2 BACKGROUND ESTIMATION

The details of the background estimation techniques used in the  $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$  analysis are discussed in section 5.5. As that section refers to a later iteration of the analysis, a general discussion is given

here for completeness. The dominant backgrounds are SM  $WW$  production and top (both pair and single) production, and these backgrounds have their normalizations estimated from dedicated control regions while their shapes are taken from simulation. The  $W+jets$  background estimate is taken entirely from data using a control sample with one well reconstructed lepton and one anti-identified lepton. All other backgrounds are taken purely from simulation.

#### 4.5.3 RESULTS

Figure 4.3 shows the  $m_T$  distribution in the  $n_j \leq 1$  channels for 8 TeV data. (No events are observed in data in the  $n_j \geq 2$  channels in this dataset). The excess shown here relatively flat as a function of hypothesized Higgs mass. The combined 7 and 8 TeV data gives an excess with local significance of  $2.8\sigma$  with an expected significance of  $2.3\sigma$ , corresponding to a  $\mu$  measurement of  $1.3 \pm 0.5$ .

**Figure 4.3:**  $m_T$  distribution in the  $H \rightarrow WW \rightarrow e\nu\mu\nu$   $n_j \leq 1$  channels for 8 TeV data[8].

#### 4.6 COMBINED RESULTS

The statistical interpretation of the combined results is undertaken as described in section 3.6.2, with a hypothesis test based on a likelihood ratio parameterized by the Higgs signal strength  $\mu$ . The null hypothesis corresponds to  $\mu = 0$ , while the SM Higgs corresponds to  $\mu = 1$ .

Table 4.3 summarizes the properties of the individual channels as well as the significances of the excesses seen. The most significant observed local excess comes from the  $\gamma\gamma$  channel. Figure 4.4 shows a comparison of the observed local  $p_0$  values as a function of hypothesized mass for the three different search channels. Both the  $ZZ^*$  and  $\gamma\gamma$  channels have very peaked excesses, while the  $WW^*$  excess can be seen as very broad because the  $m_T$  distribution does not provide detailed information about the true Higgs mass.

Channel	Fit var.	Observed $Z_l$	Expected $Z_l$	$\hat{\mu}$
$H \rightarrow ZZ^* \rightarrow 4\ell$	$m_{4\ell}$	3.6	2.7	$1.2 \pm 0.6$
$H \rightarrow \gamma\gamma$	$m_{\gamma\gamma}$	4.5	2.5	$1.8 \pm 0.5$
$H \rightarrow WW^* \rightarrow e\nu\mu\nu$	$m_T$	2.8	2.3	$1.3 \pm 0.5$
Combined	-	6.0	4.9	$1.4 \pm 0.3$

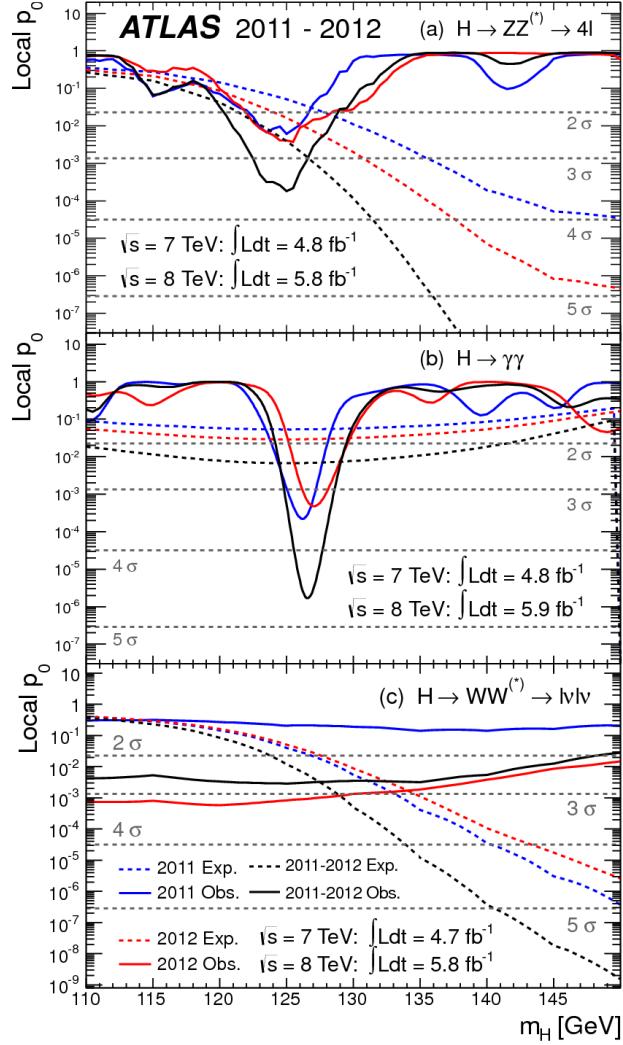

**Table 4.3:** Summary of the expected and observed significance and measured signal strengths in the combined 7 and 8 TeV datasets for the Higgs discovery analysis[8].

Figure 4.5 shows the combined exclusion limit,  $p_0$ , and signal strength. The highest local excess comes at a value of 126.5 GeV and corresponds to a  $6.0\sigma$  observed excess.

Figure 4.6 shows a comparison of the measured signal strengths between the different Higgs search channels. All measured  $\mu$  are consistent with unity within their uncertainty, and the combined  $\mu$  measurement is  $1.4 \pm 0.3$ .

The likelihood can also be computed in a two-dimensional plane of  $m_H$  and  $\mu$ , and this is shown in figure 4.7. The figure shows that while the  $\gamma\gamma$  and  $ZZ^*$  channels have very good mass resolution, the excess in  $WW^*$  covers a broad mass range. The banana shape of the  $WW^*$  result is due to the fact that the excess in this channel can either be explained by increasing the signal strength or by changing the mass (and thus the cross section). The two parameters are correlated due to the lack of mass sensitivity in this channel.

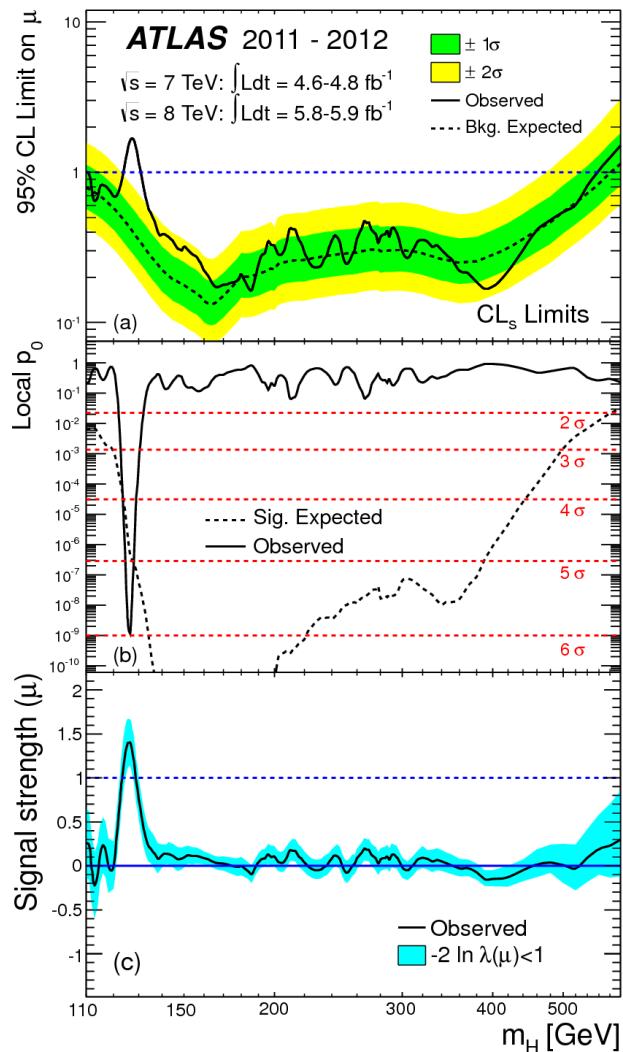

Because multiple Higgs mass points are searched for, the local significance must be corrected for a look-elsewhere effect to compute a true global significance. The global significance for finding a Higgs anywhere in the mass range of 110 GeV to 600 GeV is  $5.1\sigma$ . This increases slightly to  $5.3\sigma$  if only mass range from 110 to 150 GeV.

**Figure 4.4:** Local  $p_0$  distribution as a function of hypothesized Higgs mass for the  $H \rightarrow ZZ^* \rightarrow 4\ell$  (a),  $H \rightarrow \gamma\gamma$  (b), and  $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$  (c) channels. Dashed curves show expected results, while solid curves show observed. Red curves are from 7 TeV data, blue curves from 8 TeV, and black curved combined[8].

#### 4.7 CONCLUSION

A search for the production of a Standard Model Higgs boson was conducted in  $4.8 \text{ fb}^{-1}$  collected at  $\sqrt{s} = 7 \text{ TeV}$  and  $5.8 \text{ fb}^{-1}$  at  $\sqrt{s} = 8 \text{ TeV}$ . A new particle consistent with the Higgs boson was observed, with a mass of  $126.5 \text{ GeV}$  and a global (local) significance of  $5.1(6.0)\sigma$ . This is the first discovery level observation of a particle consistent with the Higgs.

**Figure 4.5:** Combined 95% CL limits (a), local  $p_0$  values (b), and signal strength measurement (c) as a function of Higgs mass[8].

## Observation of Vector Boson Fusion

production of  $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$

### 5.1 INTRODUCTION

After the discovery of a particle consistent with the Higgs boson, the  $H \rightarrow WW^*$  analysis had two main goals. The first goal was to increase the sensitivity of the analysis to fully confirm that the  $H \rightarrow WW^*$  process did indeed exist. The second goal was to characterize the particle as much as possible, including searching for the lower cross-section production modes, in order to confirm that it was indeed a Higgs boson. This chapter presents a dedicated search for Vector Boson Fusion (VBF) production of a Higgs boson decaying via the  $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$  mode. First, basics of the topology of VBF production are presented. Then, the details of the analysis are shown, including signal region definition, background estimation techniques, and systematic uncertainties. Finally, the results of the analysis are shown. As will

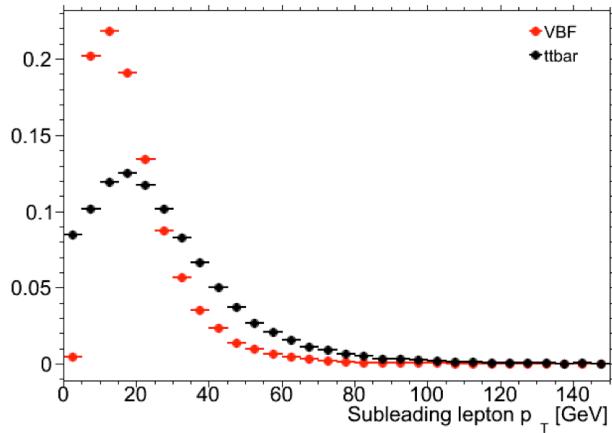

be shown, this analysis is the first and most sensitive observation of the VBF production mode of the Higgs on ATLAS.

## 5.2 DATA AND SIMULATION SAMPLES

The results presented here are with  $20.3 \text{ fb}^{-1}$  taken at  $\sqrt{s} = 8 \text{ TeV}$  and  $4.5 \text{ fb}^{-1}$  taken at  $\sqrt{s} = 7 \text{ TeV}$ . The details of the LHC and detector conditions during this period are given in Chapter 2. The trigger selection defining the dataset is discussed in section 5.2.1. The simulation samples used for signal and background modeling are given in section 5.2.2.

### 5.2.1 TRIGGERS

The analysis uses a combination of single lepton and dilepton triggers to allow lowering of the  $p_T$  thresholds and increased signal acceptance. The  $p_T$  threshold on the leptons is a particularly important consideration for this signal. Because the second  $W$  produced in the decay can be off-shell, it tends to produce lower momentum leptons. Thus, being able to lower the  $p_T$  threshold while still maintaining a low background rate is critical. Figure 5.1 shows an example of the subleading lepton  $p_T$  for a VBF  $H \rightarrow WW^*$  signal compared to the corresponding  $t\bar{t}$  background. Note that the lepton  $p_T$  spectrum is considerably softer in the signal sample.

**Figure 5.1:** A comparison of the subleading lepton  $p_T$  spectrum between VBF  $H \rightarrow WW^*$  production and  $t\bar{t}$  background

As discussed in Chapter 2, there are multiple levels in the ATLAS trigger system, and there are different  $p_T$  thresholds imposed for the leptons at each level. Additionally, some triggers have a loose selection on the isolation of the lepton (looser than that applied offline in the analysis object selection). Table 5.1 shows the thresholds used for single lepton triggers, while table 5.2 shows the thresholds coming from di-lepton triggers. The single lepton trigger efficiency for muons that pass the analysis object selection is 70% for muons in the barrel region ( $|\eta| < 1.05$ ) and 90% in the endcap region. The electron trigger efficiency increases with electron  $p_T$  but the average is approximately 90%. These efficiencies are measured by combined performance and trigger signature groups[44, 45].

	Level-1 threshold	High-level threshold
Electron	18	$24i$
	30	60
Muon	15	$24i$
		36

**Table 5.1:** Single lepton triggers used for electrons and muons. A logical “or” of the triggers listed for each lepton type is taken. Units are in GeV, and the  $i$  denotes an isolation requirement in the trigger.

	Level-1 threshold	High-level threshold
$ee$	10 and 10	12 and 12
$\mu\mu$	15	18 and 8
$e\mu$	10 and 6	12 and 8

**Table 5.2:** Di-lepton triggers used for different flavor combinations. The two thresholds listed refer to leading and sub-leading leptons, respectively. The di-muon trigger only requires a single lepton at level-1.

The combination of all triggers shown gives good efficiency for signal events. This efficiency is summarized in table 5.3. The relative improvement in efficiency by adding the dilepton triggers is also shown in the same table. The largest gain comes in the  $\mu\mu$  channel. Overall the trigger selection shows a good efficiency for  $H \rightarrow WW^*$  signal events.

### 5.2.2 MONTE CARLO SAMPLES

Modeling of signal and background processes in the signal region, in particular for the  $m_T$  distribution, is an important consideration for the final interpretation of the analysis. Therefore, careful consideration

Channel	Trigger efficiency	Gain from $2\ell$ trigger
$ee$	97%	9.1%
$\mu\mu$	89%	18.5%
$e\mu$	95%	8.3%
$\mu e$	81%	8.2%

**Table 5.3:** Trigger efficiency for signal events and relative gain of adding a dilepton trigger on top of the single lepton trigger selection. The first lepton is the leading, while the second is the sub-leading. Efficiencies shown here are for the ggF signal in the  $n_j = 0$  category but are comparable for the VBF signal.

must be paid to which Monte Carlo (MC) generators are used for specific processes. With the exception of the  $W + \text{jet}$  and multijet backgrounds, the  $m_T$  shape used as the final discriminant is taken from simulation. (Many backgrounds are normalized from data, as described in section 5.5).

Table 5.4 shows the MC generators used for the signal and background processes, as well as their cross sections. In order to include corrections up to next-to-leading order (NLO) in the QCD coupling constant  $\alpha_s$ , the **POWHEG** [46] generator is often used. In some cases, only leading order generators like **ACERMC** [47] and **GG2VV** [48] are available for the process in question. If the process requires good modeling for very high parton multiplicities, the **SHERPA** [49] and **ALPGEN** [50] generators are used to provide merged calculations for five or fewer additional partons. These matrix element level calculations must then be additionally matched to models of the underlying event, hadronization, and parton shower. There are four possible generators for this: **SHERPA**, **PYTHIA 6**[51], **PYTHIA 8**[52], or **HERWIG** [53] + **JIMMY** [54]. The simulation additionally requires an input parton distribution function (PDF). The **CT10**[55] PDFs are used for **SHERPA** and **POWHEG** simulated samples, while **CTEQ6L1**[56] is used for **ALPGEN + HERWIG** and **ACERMC** simulations. The Drell-Yan samples are reweighted to the **MRST** [57] PDFs, as these are found to give the best agreement between data and simulation.

Once the basic hard scattering process is simulated, it must be passed through a detector simulation and additional pile-up events must be overlaid. The pile-up events are modeled with **PYTHIA 8**, and the ATLAS detector is simulated with **GEANT4**[58]. Because of the unique phase space of the  $H \rightarrow WW^*$  analysis, events are sometimes filtered at generator level to allow for more efficient generation of relevant events. The efficiency of the trigger in MC simulation does not always match the measured efficiency in data, so trigger scale factors are applied to correct the MC efficiency to the data. These are derived by the

### 5.3 OBJECT SELECTION

In order to define the signal region, the analysis must first select the objects to be considered. The details of the object reconstruction algorithms are discussed in Chapter 2, while this section gives specific selection cuts used in the  $H \rightarrow WW^*$  analysis.

The first step in this process is to select a primary vertex candidates. The event's primary vertex is the vertex with the largest sum of  $p_T^2$  for associated tracks and is required to have at least three tracks with  $p_T > 450$  MeV. Many of the object selection cuts are then made relative to this chosen primary vertex.

#### 5.3.1 MUONS

The analysis uses combined muon candidates, where a track in the Inner Detector has been matched to a standalone track in the Muon Spectrometer. The track parameters are combined statistically in the muon reconstruction algorithm[59]. The muons are required to be within  $|\eta| < 2.5$  and have a  $p_T > 10$  GeV. To reduce backgrounds coming from mis-reconstructed leptons, there are requirements on the impact parameter of the muon relative to the primary vertex. The transverse impact parameter  $d_0$  is required to be small relative to its estimated uncertainty, the exact cut value being  $d_0/\sigma_{d_0} < 3$ . The longitudinal impact parameter  $z_0$  must satisfy  $|z_0 \sin \theta| < 1$  mm.

As discussed previously, the muons must also be isolated. There are two types of lepton isolations that are calculated: track-based and calorimeter-based. For muons, the track-based isolation is defined using the scalar sum  $\sum p_T$  for tracks with  $p_T > 1$  GeV (excluding the muon's track) within a cone of  $\Delta R = 0.3$  ( $0.4$ ) for muon with  $p_T > 15$  GeV ( $10 < p_T < 15$  GeV). The final isolation requirement is made by requiring that this scalar sum be no more than a certain fraction of the muon's  $p_T$ . This requirement varies with muon  $p_T$  and the exact cuts are defined in table 5.5.

The calorimeter-based muon isolation is defined using as a  $\sum E_T$  calculated from calorimeter cells using the same cone size as the track-based isolation but excluding cells with  $\Delta R < 0.05$  around the muon. This requirement is also defined as a cut on the ratio of the sum to the muon  $p_T$  and varies with muon  $p_T$ . The cut values are also given in table 5.5.

The isolation requirements loosen as a function of  $p_T$  to allow for larger signal acceptance. At low  $p_T$ ,

the isolation is tightened to reduce the  $W + \text{jets}$  background which arises from a misidentified lepton.

$p_T$ range (GeV)	Calorimeter isolation	Track isolation
10 – 15	0.06	0.06
15 – 20	0.12	0.08
20 – 25	0.18	0.12
> 25	0.30	0.12

**Table 5.5:**  $p_T$  dependent isolation requirements for muons. Muons are required to have the amount of calorimeter or track based cone sums be less than this fraction of their  $p_T$ .

### 5.3.2 ELECTRONS

Electrons are identified by matching reconstructed clusters in the electromagnetic calorimeter with tracks in the inner detector. The electrons are identified using a likelihood based method[60, 61] which takes into account the shower shapes in the calorimeter, the matching of tracks to clusters, and the amount of transition radiation in the TRT. The electrons are required to have  $|\eta| < 2.47$ , and candidates in the transition region between the barrel and endcap ( $1.37 < |\eta| < 1.52$ ) are excluded. As the muons, the electrons are required to have transverse impact parameter significance  $< 3$ , while in the longitudinal direction they must have  $|z_0 \sin \theta| < 0.4$  mm. Some electron requirements also vary with electron  $E_T$ , and these requirements are summarized in table 5.6.

The isolation for electrons are defined similarly to the muons but with unique cuts on the objects included. The track-based isolation is defined using tracks with  $p_T > 400$  MeV with cone sizes as defined previously. The calorimeter-based isolation also uses the same cone size as the muon, but here the cells within a  $0.125 \times 0.175$  area in  $\eta \times \phi$  around the electron cluster's barycenter are excluded. The other difference with respect to muons is that the denominator of the isolation ratio is the electron's  $E_T$  rather than  $p_T$ . The isolation cuts very with electron  $E_T$  and are defined in table 5.6.

The electron is also required to not be consistent with a vertex coming from a photon conversion.

### 5.3.3 JETS

Jets are clustered with the anti- $k_T$  reconstruction algorithm using a radius parameter of  $R = 0.4$ . They are required to have a jet vertex fraction (JVF) of at least 50%, meaning that half of the tracks associated

$p_T$ range (GeV)	Quality cut	Calorimeter isolation	Track isolation
10 – 15	Very tight LH	0.20	0.06
15 – 20	Very tight LH	0.24	0.08
20 – 25	Very tight LH	0.28	0.10
> 25	Medium	0.28	0.10

**Table 5.6:**  $p_T$  dependent requirements for electrons. Electrons are required to have the amount of calorimeter or track based cone sums be less than this fraction of their  $E_T$ .

with the jet originated from the primary vertex. Jets with no tracks associated (i.e. those outside the acceptance of the ID) do not have this requirement applied. Jets are required to have  $p_T > 25$  GeV if they are within the tracking acceptance ( $|\eta| < 2.4$ ). Jets with  $2.4 < |\eta| < 4.5$  are required to have  $p_T > 30$  GeV. This tighter requirement reduces jets from pileup in the region where JV requirements cannot be applied. The two highest  $p_T$  jets in the event are referred to as the “VBF” jets and used to compute various analysis selections later.

Identification of  $b$ -jets is done using the MV1 algorithm and is limited to the acceptance of the ID ( $|\eta| < 2.5$ ). The operating point of MV1 that is used is the one that is 85% efficient for identifying true  $b$ -jets. This operating point has a 10.3% of mis-tagging a light quark jet as a  $b$ -jet. In order to improve the rejection of  $b$ -jets, a lower threshold than the nominal  $p_T$  threshold described above is used. For the purposes of counting the number of  $b$ -jets, jets with  $p_T$  down to 20 GeV are used.

#### 5.3.4 OVERLAP REMOVAL

There are some cases where certain reconstructed objects will overlap and one will have to be chosen (for example, an electron and a jet in the calorimeter). First, the case of lepton overlap is dealt with. If an electron candidate extends into the muon spectrometer, it is removed. If a muon or electron have a  $\Delta R < 0.1$ , the electron is removed and the muon is kept. If two electron candidates overlap within the same radius, then the higher  $E_T$  electron is kept. Next, the overlap between leptons and jets is considered. If an electron and jet are within  $\Delta R < 0.3$  of one another, the electron is kept and the jet is removed. However, if a muon and jet overlap within  $\Delta R < 0.3$ , the jet is kept (as it is likely that the muon is the result of a semileptonic decay inside the jet).

Once the overlap removal is complete, the final set of objects used in the analysis is defined.

## 5.4 ANALYSIS SELECTION

The VBF analysis uses two distinct selections. The first is a looser selection that uses a Boosted Decision Tree (BDT) score as the final discriminator in order to take advantage of the detailed correlations between the VBF variables. The second is a more standard selection, referred to as “cut-based”, that applies cuts on the VBF variables and uses  $m_T$  as the final discriminating variable. While the BDT analysis is ultimately more sensitive, the cut-based serves as an important component of the analysis. First, the cut-based allows for confirming the modeling and validity of many variables used as input to the BDT. Second, because this is the first use of such an MVA technique in the  $H \rightarrow WW^*$  analysis, the cut-based selection allows confirmation of the final BDT result with a more traditional analysis. Both analyses will be discussed here.

One important note is that because this analysis is dedicated to the measurement of the VBF production mode of the Higgs, events coming from gluon fusion production with the Higgs decaying via  $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$  are treated as background events. This will be seen throughout the various cutflow tables and yields shown.

### 5.4.1 COMMON PRE-SELECTION

Both the BDT and cut-based analyses have a common pre-selection that is applied before their main cuts. The cuts on leptons are common to all  $n_j$  bins. The analysis requires two oppositely charged leptons, with the leading lepton required to have  $p_T > 22$  GeV while the subleading lepton must have  $p_T > 10$  GeV. Next, to cut out low mass  $Z/\gamma^*$  events, a cut on the dilepton mass  $m_{\ell\ell} > 10$  (12) GeV is applied in the different (same) flavor channel. In the same flavor channels, there is an additional veto placed on the region around the Z peak, requiring that  $|m_{\ell\ell} - m_Z| > 15$  GeV.

There are also requirements on the amount of missing transverse momentum in the event. These are only applied in the same flavor channels, as in the different flavor channels  $t\bar{t}$  is the dominant background in  $n_j \geq 2$ . The BDT analysis requires  $p_T^{\text{miss}} > 40$  GeV and  $E_T^{\text{miss}} > 45$  GeV. The cut-based analysis must cut tighter on these variables to have maximal sensitivity and thus requires  $p_T^{\text{miss}} > 50$  GeV and  $E_T^{\text{miss}} > 55$  GeV.

Finally, because this analysis is focused on VBF, a requirement on the jet multiplicity is placed, with  $n_j \geq 2$ . Additionally, the analysis requires that there are no jets identified as b-quarks in the event, or  $n_b = 0$ .

#### 5.4.2 CUT-BASED SELECTION

The cut-based selection places sequential requirements on variables reconstructed from the VBF jets in order to increase the signal to background ratio.

#### GENERAL BACKGROUND REDUCTION

Top pair production is the primary background in the  $n_j \geq 2$  bin. Even though  $n_b = 0$  is required, an additional variable is constructed to further suppress the top background. There is often additional QCD radiation that accompanies the  $t\bar{t}$  system when it is produced. Therefore, a variable which tests for the presence of this additional radiation,  $p_T^{\text{sum}}$ , is constructed. It is defined in equation 5.1.

$$p_T^{\text{sum}} = p_T^{\ell\ell} + p_T^{\text{miss}} + \sum p_T^j \quad (5.1)$$

The first cut after pre-selection in the cut-based analysis requires  $p_T^{\text{sum}} < 15$  GeV to further suppress  $t\bar{t}$  production.

In the different flavor channels, a cut is made to reduce the contamination from  $Z \rightarrow \tau\tau$  decays. The di- $\tau$  invariant mass,  $m_{\tau\tau}$ , is constructed by assuming that the neutrinos from the  $\tau$  decays were collinear with the leptons[? ]. The analysis requires that this mass not be consistent with a  $Z$  by requiring  $m_{\tau\tau} < m_Z - 25$  GeV.

#### VBF TOPOLOGICAL CUTS

The characteristic feature of VBF production of the Higgs is the presence of two additional forward jets coming from the incoming partons which radiate the vector bosons that make the Higgs. These jets are forward because the outgoing partons still carry the longitudinal momentum of the incoming partons. Figure 5.2 shows the distribution of the  $\eta$  for the leading jet in a VBF event compared to a background

top pair production event. As can be seen, the VBF jets tend to be more forward in  $\eta$ , while the  $t\bar{t}$  jets are more central.

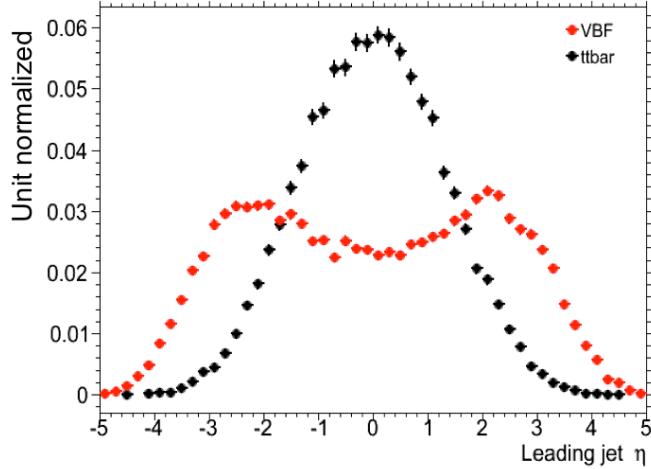

Figure 5.2: Leading jet  $\eta$  in VBF  $H \rightarrow WW^*$  (red) and  $t\bar{t}$  (black)

Because the cross section for VBF production is an order of magnitude smaller than gluon fusion production, these forward jets must be used in order to better reduce background and achieve a good signal to background ratio. The dedicated VBF search selection requirements are constructed to maximally exploit the features of the unique VBF topology.

Requirements on the VBF jets are collectively referred to as the “VBF topological cuts”. First, a requirement on the dijet invariant mass of the VBF jets,  $m_{jj}$ , is placed, requiring  $m_{jj} > 600$  GeV. Next, the event is required to have a large gap in rapidity between the two VBF jets, or  $\Delta y_{jj} > 3.6$ . Both of these cuts put tight requirements on the presence of two forward, high  $p_T$  jets moving in opposite directions in the longitudinal plane.

Beyond requiring the presence of the two forward VBF jets, the analysis also vetoes on the presence of any additional jets that fall between the two VBF jets. This cut is referred to as the central jet veto, or CJV. Any events with a third jet with  $p_T > 20$  GeV whose rapidity is between the region defined by the two VBF jets are vetoed. This can be expressed in terms of a variable called the jet centrality, defined in

equation 5.2.

$$C_{j3} = \left| \eta_{j3} - \frac{\eta_{j1} + \eta_{j2}}{2} \right| / \frac{|\eta_{j1} - \eta_{j2}|}{2}, \quad (5.2)$$

Here,  $\eta_{j1}$  and  $\eta_{j2}$  are the pseudorapidities of the leading and subleading jets, respectively, while  $\eta_{j3}$  is the pseudorapidity of the extra jet in the event (if one exists). Intuitively,  $C_{j3}$  is zero when  $\eta_{j3}$  is directly centered between the two jets and unity when  $\eta_{j3}$  is aligned with either of the VBF jets. Thus, the CJV can be expressed as a requirement that  $C_{j3} > 1$ .

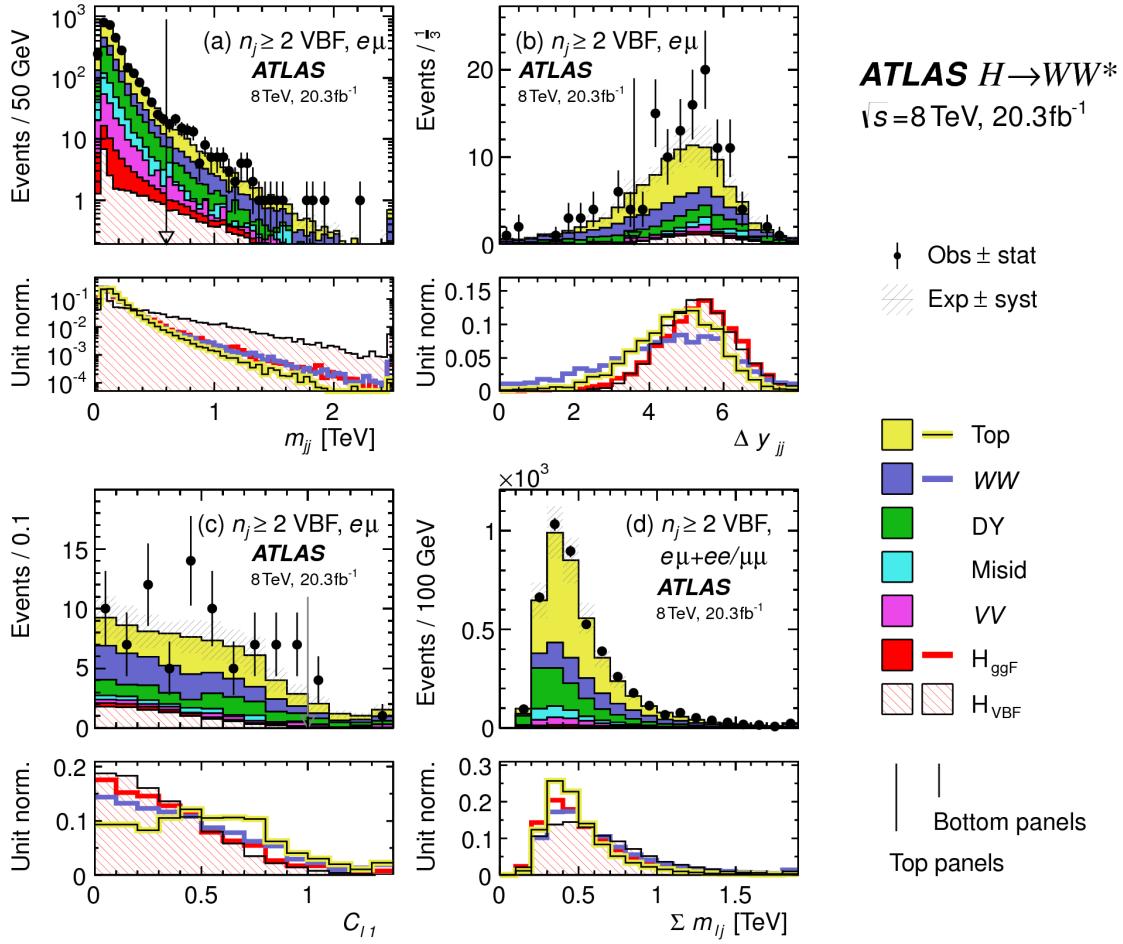

The decay products of the Higgs tend to be central as well. Thus, the analysis also requires that both leptons in the analysis fall within the rapidity gap defined by the jets. This cut is referred to as the outside lepton veto, or OLV. A quantitative way to define the cut is to require that the centrality of each lepton (defined analogously to that of the third jet in equation 5.2) correspond to the lepton being within the jet rapidity gap, or  $C_\ell < 1$  for both leptons.

Figure 5.3a-c shows the  $m_{jj}$ ,  $\Delta y_{jj}$ , and  $C_{\ell 1}$  variables at the stage where all previous cuts in the sequence have been made. The agreement between data and Monte Carlo is good, and the bottom panels show their power in discriminating the VBF signal from the background processes.

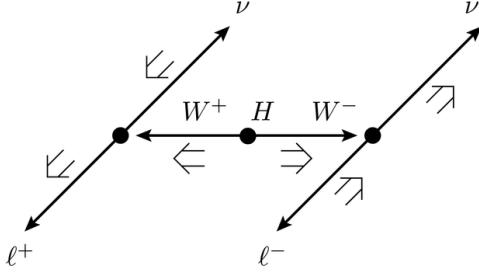

The final signal region is also split into two bins of  $m_{jj}$ , with the first bin corresponding to  $600 \text{ GeV} < m_{jj} < 1 \text{ TeV}$  and the second bin corresponding to  $m_{jj} > 1 \text{ TeV}$ . The first bin has more statistics but also a larger contribution from background, while the second bin has lower statistics but a 1:1 signal to background ratio.

## HIGGS TOPOLOGICAL CUTS

The final state leptons will exhibit unique correlations due to the fact that they are arising from the decay of a spin zero resonance. In particular, the spins of the final state leptons and neutrinos must all cancel, as shown in figure 5.4. Because the neutrino has a left handed chirality and the anti-neutrino has a right handed chirality (in the massless neutrino approximation), the spin and momentum of the particles will be anti-aligned and aligned, respectively. In the transverse plane, the momenta of all four final state objects must cancel as well. With the constraint of having both the momenta and the spin alignments

**Figure 5.3:** Distributions of (a)  $m_{jj}$ , (b)  $\Delta y_{jj}$ , (c)  $C_{\ell 1}$ , and (d)  $\sum m_{ij}$ , for the VBF analysis. The top panels compare simulation and data, while the bottom panels show normalized distributions for all background processes and signal[7].

**Figure 5.4:** A cartoon of the  $WW$  final state. Momenta are represented with thin arrows, spins with thick arrows. [7]

cancel, the final state kinematics strongly prefer having a small angle between the leptons in the transverse plane (low  $\Delta\phi_{\ell\ell}$ ). This angular correlation will also lead to low values of the di-lepton invariant mass  $m_{\ell\ell}$ . These unique signal final state kinematic correlations will be exploited to define the ultimate signal region.

The analysis places additional requirements on the final state leptons. Two requirements on dilepton kinematics are made that are common with lower multiplicity jet bins as well. The angle between leptons in the transverse plane,  $\Delta\phi_{\ell\ell}$ , is required to be less than 1.8 radians. Additionally, the dilepton mass  $m_{\ell\ell}$  is required to be less than 50 GeV.

The cut-based analysis uses  $m_T$  as the final discriminating variable as in the ggF focused analysis. The optimal number of bins in  $m_T$  was found to be three bins, with the bin boundaries at 80 and 130 GeV.

Table 5.7 shows the data and estimated signal and background yields from simulation as each cut described above is made. The table shows how each cut reduces specific backgrounds and how the overall signal to background ratio grows through the cutflow.

Figure 5.5 shows an ATLAS event display of a candidate event in the final signal region.

#### 5.4.3 BDT BASED SELECTION

The boosted decision tree based analysis takes a different philosophy compared to the cut-based. Rather than cutting sequentially on many variables, the BDT analysis uses many of these variables as inputs to the BDT and the output BDT score as the final discriminant. The BDT is trained with the VBF  $H \rightarrow WW^*$  simulation as the signal samples and all other processes as background, including ggF

**Table 5.7:** Event selection for the  $n_j \geq 2$  VBF analysis in the 8 TeV cut-based analysis[7].

#### PRE-TRAINING SELECTION AND BDT INPUTS

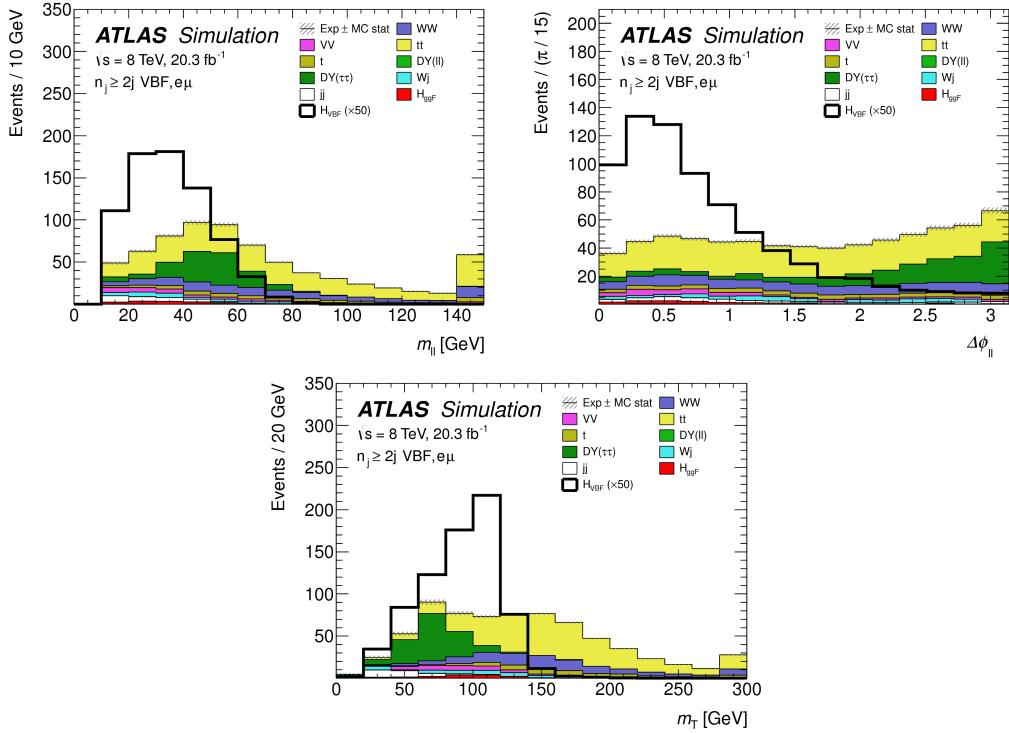

Before training, the common preselection cuts described in section 5.4.1 are applied. Additionally, the central jet veto and outside lepton veto described in section 5.4.2 are applied. The BDT has eight input variables, six of which are also variables that are used in the cut-based analysis. The six shared variables are  $p_T^{\text{sum}}$ ,  $m_{jj}$ ,  $\Delta y_{jj}$ ,  $m_{\ell\ell}$ ,  $\Delta\phi_{\ell\ell}$ , and  $m_T$ . The seventh variable input in the BDT is a combination of the variables used to do the OLV in the cut-based analysis. The BDT uses as input the sum of lepton centralities, or  $\sum C_\ell = C_{\ell 1} + C_{\ell 2}$ . The final BDT input variable,  $\Sigma m_{\ell j}$ , is constructed to account for the correlations between the jets and leptons in the event. It is the sum of the invariant masses of all four

possible lepton-jet combinations, shown in equation 5.3.

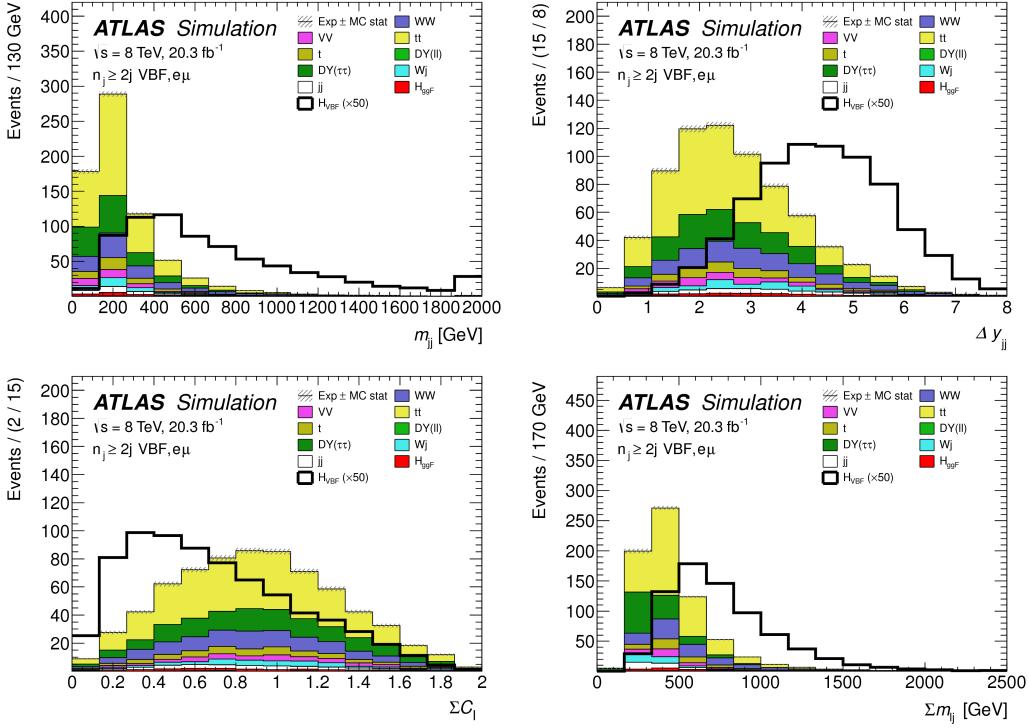

$$\Sigma m_{\ell j} = m_{\ell 1,j1} + m_{\ell 1,j2} + m_{\ell 2,j1} + m_{\ell 2,j2} \quad (5.3)$$

Figure 5.3d shows the agreement between data and simulation for the  $\Sigma m_{\ell j}$  variable, as well as showing its discriminating power. Figure 5.6 shows the distributions of the Higgs topological variables used as BDT inputs for VBF signal and corresponding backgrounds. Figure 5.7 shows the distributions of the VBF topological variables used as BDT inputs. In both cases, the VBF yield has been scaled by a factor of 50 to better show the shape difference compared to the backgrounds.

Table ?? summarizes the cuts applied for the BDT and cut-based analyses, as well as which variables are used as input to the BDT.

**Figure 5.6:** Distributions of  $m_{\ell\ell}$  (top left),  $\Delta\phi_{\ell\ell}$  (top right), and  $m_T$  (bottom) for the VBF BDT analysis. These are plotted after all of the BDT pre-training selection cuts[7].

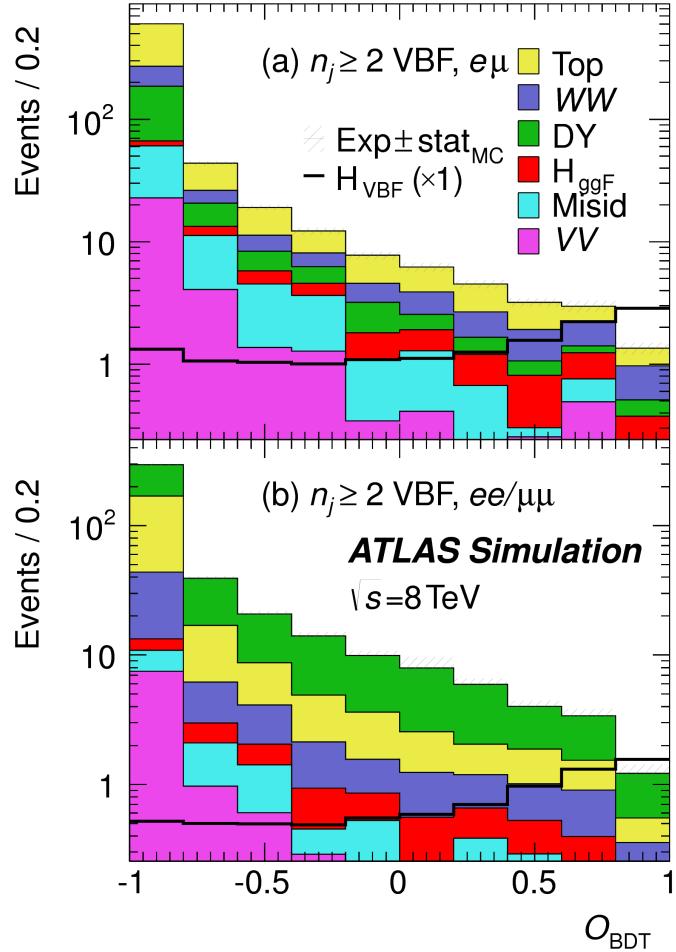

**Figure 5.7:** Distributions of  $m_{jj}$  (top left),  $\Delta y_{jj}$  (top right),  $\sum C_\ell$  (bottom left), and  $\sum m_{\ell j}$  (bottom right) for the VBF BDT analysis. These are plotted after all of the BDT pre-training selection cuts[7].

## BDT OUTPUT

After training, the BDT outputs a score ( $O_{\text{BDT}}$ ) which is in the range  $[-1, 1]$ , where  $-1$  corresponds to background-like events and  $+1$  corresponds to signal-like events. Figure 5.8 shows the output BDT distribution in both the different flavor and same flavor channels. For the final discriminant analysis, the  $O_{\text{BDT}}$  distribution is divided into four bins, with boundaries at  $[-1, -0.48, -0.3, 0.78, 1]$ . The bins are numbered from 0, 1, 2, 3 respectively. Because bin 0 is predominantly background, it is excluded from the likelihood analysis.

## 5.5 BACKGROUND ESTIMATION

This section describes the procedures used to estimate backgrounds for the VBF analysis in both the cut-based and BDT analyses.

**Figure 5.8:** Distributions of  $O_{\text{BDT}}$  for the VBF signal and associated backgrounds after the VBF pre-training selection[7].

### 5.5.1 GENERAL STRATEGY

Most of the backgrounds in the VBF analysis have shapes estimated from Monte Carlo simulation but normalizations derived from control regions in data. In essence, a normalization factor (denoted with  $\beta$  or abbreviated as NF) is derived by scaling the MC yield in the control region to the corresponding yield in data. Once this factor is derived, it can be used to scale the MC estimate of the background in the signal region. This is illustrated in equation 5.4.

$$B_{\text{SR}}^{\text{est}} = B_{\text{SR}} \times \frac{N_{\text{CR}}}{B_{\text{CR}}} \equiv B_{\text{SR}} \times \beta \quad (5.4)$$

Here,  $B$  denotes the MC yield prediction in the denoted region, while  $N$  denotes the observed number of events in data in the denoted region.

Another way of writing the same equation, in terms of an extrapolation factor  $\alpha$  rather than a normalization factor  $\beta$ . The overall calculation is exactly the same. However, when phrased in this way, it shows how the uncertainty on the background estimation can be reduced. This is shown in equation 5.5.

$$B_{\text{SR}}^{\text{est}} = N_{\text{CR}} \times \frac{B_{\text{SR}}}{B_{\text{CR}}} \equiv N_{\text{CR}} \times \alpha \quad (5.5)$$

Phrased this way, the equation shows that with enough statistics in the control region, a large theoretical uncertainty on the overall background yield in the signal region can be replaced by a small statistical uncertainty coming from the number of data events in the CR and a smaller theoretical uncertainty on the extrapolation from the control region to the signal region.

### 5.5.2 TOP BACKGROUND

The normalization factor  $\beta_t$  for the top background in the VBF analysis is derived in a region required to have one b-tagged jet, or  $n_b = 1$ . In the cut-based analysis, normalization factors are computed at every stage of the cutflow by applying the appropriate cuts in the CR. These NF are then applied to the  $t\bar{t}$  and single top event yields in the SR. In the BDT analysis, a single normalization factor is computed for each bin of  $O_{\text{BDT}}$  after applying the BDT pre-training cuts described previously. The computed normalization factors are derived with all flavor combinations combined in order to decrease statistical uncertainty. Additionally, in the BDT analysis, BDT bins 2 and 3 are merged for the same reason.

Table 5.8 shows the evolution of the  $\beta_t$  through the cut-based selection. Table 5.9 shows the value of the  $\beta_t$  in each bin of  $O_{\text{BDT}}$ . In all cases, the computed factors are relatively consistent with unity, with the largest discrepancy coming in bin 1 of  $O_{\text{BDT}}$ .

Figure 5.9 shows the  $m_{jj}$  and  $O_{\text{BDT}}$  distributions in the top control region. Overall the modeling looks consistent with the data.

While these normalization factors can be computed and applied to the expected background yields listed in tables like table 5.7, in the end the normalization of the top background is profiled (meaning

Cut	$\beta_t$
$p_T^{\text{sum}} < 15 \text{ GeV}$	$1.03 \pm 0.01$
$m_{\tau\tau} < m_Z - 25$	$1.05 \pm 0.01$
$m_{jj} > 600 \text{ GeV}$	$0.96 \pm 0.06$
$\Delta y_{jj} > 3.6$	$1.02 \pm 0.08$
CJV	$1.13 \pm 0.16$
OLV	$1.01 \pm 0.19$
$m_{jj} < 1 \text{ TeV}$	$0.94 \pm 0.19$
$m_{jj} > 1 \text{ TeV}$	$1.48 \pm 0.66$

**Table 5.8:** Top normalization factors computed at each stage of the cut-based selection. Uncertainties are statistical only.

$O_{\text{BDT}}$	$\beta_t$
Bin0	$1.09 \pm 0.02$
Bin1	$1.58 \pm 0.15$
Bin2	$0.95 \pm 0.31$
Bin3	$0.95 \pm 0.31$

**Table 5.9:** Top normalization factors computed for each bin of  $O_{\text{BDT}}$ . Uncertainties are statistical only.

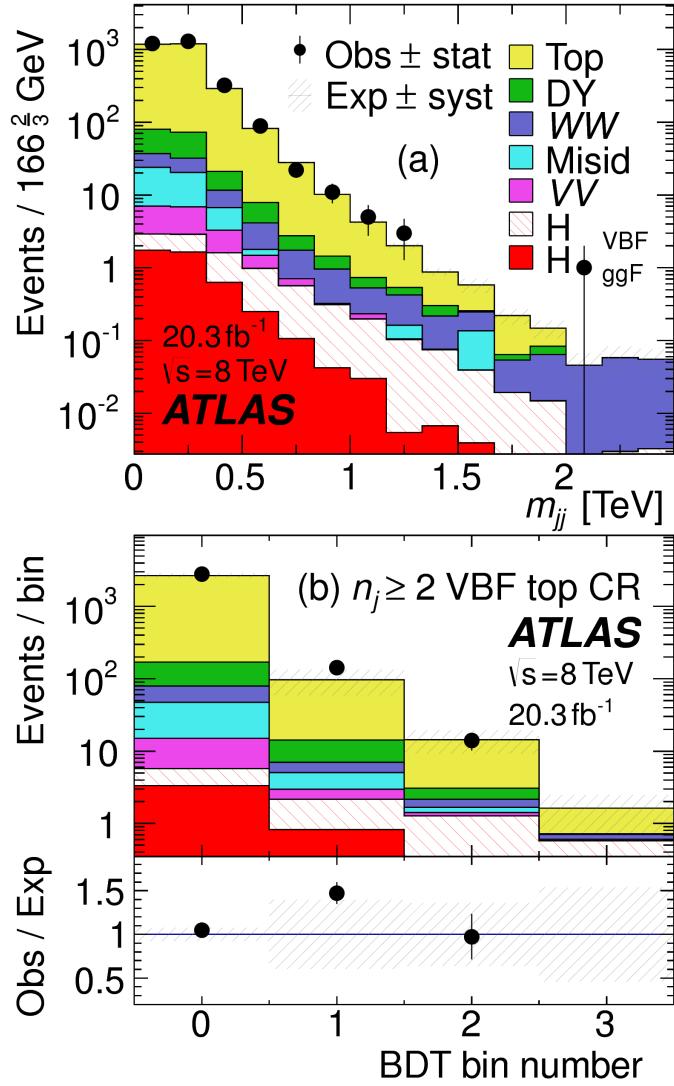

there is a dedicated Poisson constraint) and allowed to float in the final statistical fit.

### 5.5.3 $Z/\gamma^* \rightarrow \tau\tau$ BACKGROUND

In the different flavor channels, the  $Z/\gamma^* \rightarrow \tau\tau$  background is an important one. Di-tau production can produce an  $e\mu$  final state if each  $\tau$  lepton decays to a different flavor lepton.

In the BDT analysis, a single normalization factor for the background is derived. A control region is defined using the pre-training selection cuts, except requiring that  $|m_{\tau\tau} - m_Z| < 25 \text{ GeV}$  so that the region is enriched in  $Z/\gamma^* \rightarrow \tau\tau$  background. Additional requirements of  $m_{\ell\ell} < 80(75) \text{ GeV}$  in the different (same) flavor channel, as well as  $O_{\text{BDT}} > -0.48$  are applied to increase the purity of the region. The final  $\beta_{Z/\gamma^*\rightarrow\tau\tau}$  is calculated to be  $0.9 \pm 0.3$  (statistical uncertainty only). Because of the small contribution of this background in the BDT analysis and the large statistical uncertainty, no additional systematics are calculated. The final SR estimate is scaled by this  $\beta$  and not allowed to float in the fit.

The cut-based corrections are a bit more involved because they need to be applied cut by cut through the cutflow, as well as in the final signal region for the fit. The region is defined including all SR cuts

**Figure 5.9:** Distributions of  $m_{jj}$  (a) and  $O_{\text{BDT}}$  (b) in the VBF  $n_b = 1$  top CR[7].

up to the  $Z/\gamma^* \rightarrow \tau\tau$  veto, which is instead made into a Z mass peak requirement as for the BDT region. The  $m_{\ell\ell}$  cut from the BDT region is included as well. The cut-based approach aims to correct the normalization of the  $Z/\gamma^* \rightarrow \tau\tau$  background in two ways. First, an overall normalization factor is computed from the control region. However, the VBF topological cuts are not included in this region, and applying them as is done in the top CR is not feasible due to limited statistics. So, instead, correction factors (CF) to the cut efficiencies of the VBF cuts are derived in a same flavor  $Z \rightarrow \ell\ell$  control region, which has significantly more statistics. The CF is simply the ratio of the cut efficiencies in data and MC

derived in this region. In the end, the overall background estimate is given by equation 5.6.

$$N_{Z/\gamma^* \rightarrow \tau\tau}^{\text{est}} = B_{Z/\gamma^* \rightarrow \tau\tau}^{\text{SR}} \times \beta_{\tau\tau} \times \frac{\epsilon_{\text{VBF cuts}}^{\text{data}}}{\epsilon_{\text{VBF cuts}}^{\text{MC}}} \quad (5.6)$$

The hypothesis is that while the normalization correction must be derived in a dedicated region, the efficiency of the VBF cuts should not be sensitive to the type of  $Z/\gamma^*$  process and thus the larger control region can be exploited to derive the CF. Figure 5.10 shows a shape comparison for the  $m_{jj}$  variable in  $Z \rightarrow \tau\tau$  events in the signal region and  $Z \rightarrow \ell\ell$  events in the control region. The figure shows that the shapes are indeed comparable and thus any CF derived in the same flavor control region can reliably be applied in the signal region.

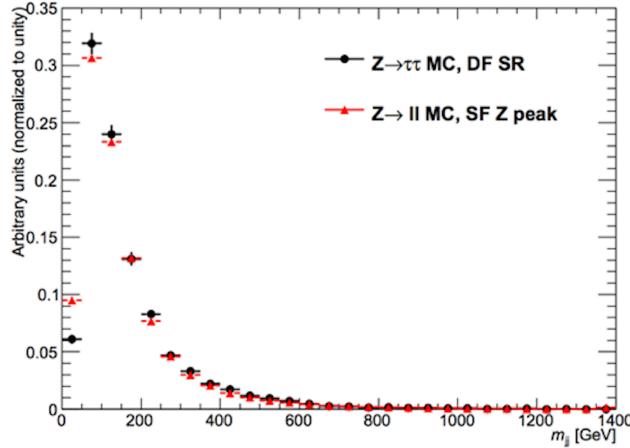

Figure 5.10: Comparison of  $m_{jj}$  shape in a same flavor  $Z \rightarrow \ell\ell$  control region and the VBF cut-based signal region.

Table 5.10 shows the overall normalization factor  $\beta_{\tau\tau}$  and the efficiency correction factors for the various VBF topological cuts. In general, the statistical uncertainties on the cut efficiency corrections are quite good, and the MC tends to underestimate the efficiency of the VBF cuts for the  $Z/\gamma^* \rightarrow \tau\tau$  background.

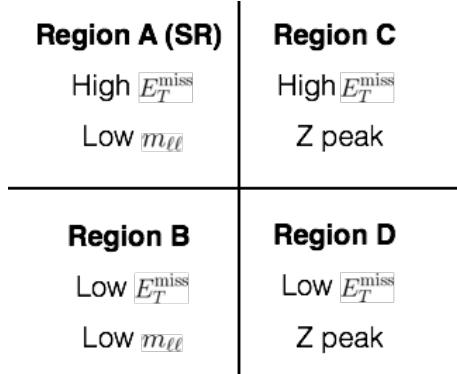

#### 5.5.4 $Z/\gamma^* \rightarrow \ell\ell$ BACKGROUND

In the same flavor channels, the  $Z/\gamma^* \rightarrow \ell\ell$  background is dominant and thus must be estimated correctly. In both the BDT and cut-based analyses, the background is estimated using the so-called

$\beta_{\tau\tau}$	$0.97 \pm 0.04$
Cut	Correction factors
$m_{jj} > 600 \text{ GeV}$	$1.09 \pm 0.01$
$\Delta y_{jj} > 3.6$	$1.14 \pm 0.02$
CJV	$1.20 \pm 0.02$
OLV	$1.17 \pm 0.03$
$m_{jj} < 1 \text{ TeV}$	$1.17 \pm 0.06$
$m_{jj} > 1 \text{ TeV}$	$1.18 \pm 0.13$

**Table 5.10:**  $Z/\gamma^* \rightarrow \tau\tau$  correction factors for the VBF cut-based analysis. Uncertainties are statistical only.

“ABCD” method. The ABCD method creates four different regions by defining cuts on two variables. One of the regions (A) is the signal region, while the other regions are defined by inverting one of both of the cuts. in this case, the two variables used are  $m_{\ell\ell}$  and  $E_T^{\text{miss}}$ , because inverting either of the SR cuts on these variables will give regions rich in the  $Z/\gamma^* \rightarrow \ell\ell$  background. Figure 5.11 illustrates the general strategy for each region.

**Figure 5.11:** General illustration of the ABCD region definitions for  $Z/\gamma^* \rightarrow \ell\ell$  background estimation.

In both of the BDT and cut-based analyses, the Z peak region is defined with  $|m_{\ell\ell} - m_Z| < 15 \text{ GeV}$ . In the BDT analysis, low  $m_{\ell\ell}$  corresponds to  $m_{\ell\ell} < 75 \text{ GeV}$  while in the cut-based it is  $m_{\ell\ell} < 50 \text{ GeV}$  (as this defines the cut-based SR). The BDT low  $E_T^{\text{miss}}$  region is between 25 and 45 GeV, while the high  $E_T^{\text{miss}}$  region is  $E_T^{\text{miss}} > 45 \text{ GeV}$ . In the cut-based, high and low  $E_T^{\text{miss}}$  are defined as opposite ends of the 55 GeV cut applied for the signal region definition.

Once the regions are defined, the final signal region background estimate is done by taking the estimate in region B and extrapolating it to the signal region (A) by multiplying it by the ratio of regions

C and D. Effectively, the  $Z$  peak region is used to estimate the efficiency of the  $E_T^{\text{miss}}$  cut in data, and then this efficiency is applied in the low  $m_{\ell\ell}$  region. An additional correction is also applied for the non-closure of the method in MC. This is summarized in equations 5.7 and 5.8.

$$N_{Z/\gamma^* \rightarrow \ell\ell}^{\text{SR}} = N_{Z/\gamma^* \rightarrow \ell\ell}^{\text{B}} \times \frac{N_{Z/\gamma^* \rightarrow \ell\ell}^{\text{C}}}{N_{Z/\gamma^* \rightarrow \ell\ell}^{\text{D}}} \times f_{\text{corr}} \quad (5.7)$$

$$f_{\text{corr}} = \frac{B_{\text{MC}}^{\text{A}}/B_{\text{MC}}^{\text{B}}}{B_{\text{MC}}^{\text{C}}/B_{\text{MC}}^{\text{D}}} \quad (5.8)$$

Here, the  $N$  refer to data yields in each region with the non  $Z/\gamma^*$  backgrounds subtracted, while  $B$  refer to the  $Z/\gamma^*$  yields in MC in each region.

A normalization factor  $\beta_{\ell\ell}$  is computed for each analysis as the ratio of the predicted data yield to the MC yield in the SR. The shape of the BDT distribution is taken from data region B, while the shape of the  $m_T$  distribution in the cut-based analysis is taken from  $Z/\gamma^*$  MC in the SR. The values of the  $\beta_{\ell\ell}$  in the BDT and cut-based analyses from this method are summarized in table 5.11. In the cut-based analysis, the same cut efficiency correction factors shown in table 5.10 are also applied (in product with the  $\beta_{\ell\ell}$ ) in the same flavor channels to this background, as they were derived in the  $Z$  peak region.

	$\beta_{\ell\ell}$
BDT Bin 1	$1.01 \pm 0.15$
BDT Bin 2	$0.89 \pm 0.28$
Cut-based	$0.81 \pm 0.21$

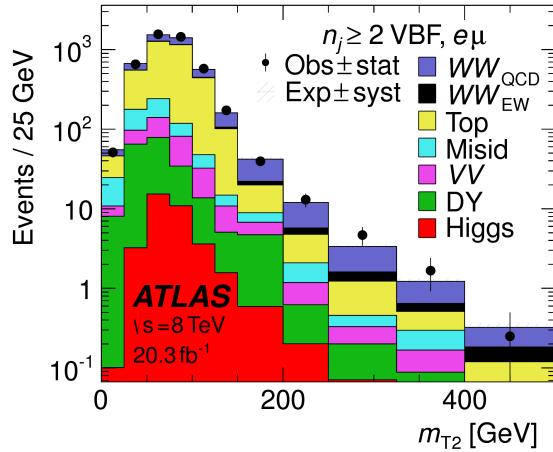

**Table 5.11:**  $Z/\gamma^* \rightarrow \ell\ell$  normalization factors for cut-based and BDT analyses. Uncertainties are statistical only.

### 5.5.5 $WW$ AND OTHER DIBOSON BACKGROUNDS

The  $WW$  and other diboson backgrounds have both their shape and normalization taken from MC simulation. They are validated in dedicated control regions and found to agree with data well.

As  $WW$  is the largest of these backgrounds and is irreducible, validating the estimate is of particular importance. The validation region is constructed by requiring the pre-selection cuts on leptons and  $m_{\ell\ell}$ ,  $n_b = 0$ , and  $m_T > 100$  GeV. The  $m_{T2}$  variable[?] is an additional discriminant that will isolate

the  $WW$  background, and a requirement of  $m_{T2} > 160$  GeV is placed to define the  $WW$  validation region. This cut gives a 60% purity for the validation region. The derived normalization factor in the region is  $1.15 \pm 0.19$  and is thus consistent with unity. Figure 5.12 shows the  $m_{T2}$  distribution and how it distinguishes the  $WW$  background.

**Figure 5.12:** Distribution of  $m_{T2}$  in the  $WW$  validation region of the VBF analysis[7].

### 5.5.6 HIGGS PRODUCTION VIA GLUON-GLUON FUSION

Because this analysis is dedicated to measuring the VBF contribution to Higgs production, the component of Higgs production from gluon-gluon fusion is treated as a background. The shape is taken directly from simulation, using the generators described in table 5.4. In the final combined fit of all different signal regions, the normalization is controlled by either a combined signal strength parameter  $\mu$ , which controls the normalization of both ggF and VBF production, or a separate parameter  $\mu_{ggF}$  depending on the interpretation being presented in the final results.

### 5.5.7 BACKGROUNDS WITH MISIDENTIFIED LEPTONS

As discussed previously, the  $W + \text{jets}$  and QCD multijet backgrounds are derived with fully data-driven methods. These backgrounds do not make a large contribution to the final VBF signal region but their estimation methods are discussed briefly here.

## $W$ +JETS BACKGROUND

The  $W$ +jets background enters the signal region by having one of the jets mis-reconstructed as a lepton. The background is estimated by constructing a control sample with two leptons, where one lepton passes the usual lepton quality cuts but the second lepton fails one of those cuts (also known as the “anti-identified” lepton). This control region is rich in the  $W$ +jets contribution because if a second lepton is reconstructed in a  $W$ +jets event it is likely to be poor quality. The purity of this  $W$ +jets control sample is 85% to 90% depending on the exact configuration of leptons in the final state.

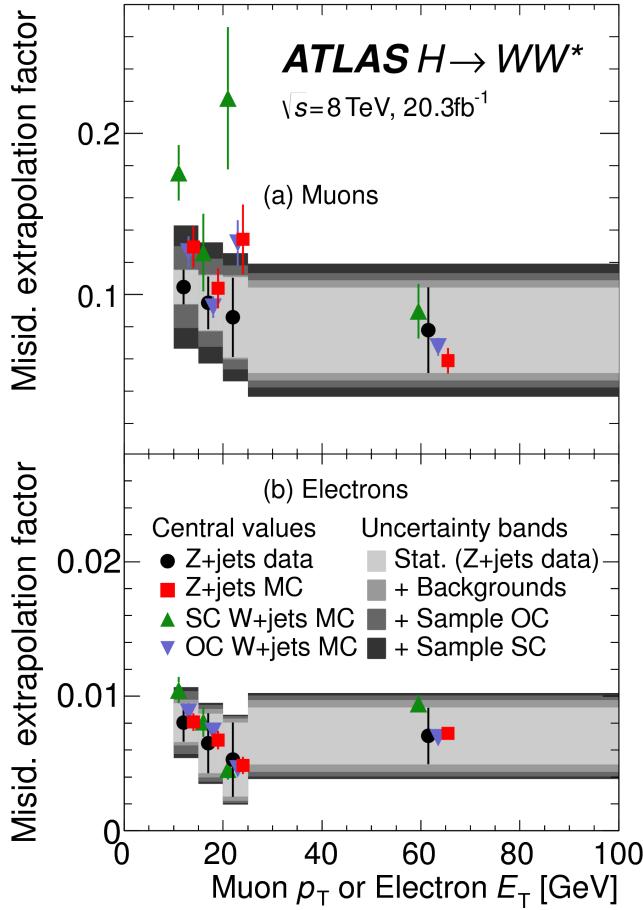

The signal region estimate of  $W$ +jets is estimated by extrapolation from the control sample to the signal region using extrapolation factors derived in a  $Z$ +jets control sample in data. The extrapolation factor is the ratio of the number of lepton candidates satisfying all quality criteria to the number of lepton candidates anti-identified. This ratio is measured in bins of  $p_T$  and  $\eta$ . Thus, the final signal region estimate (binned as the extrapolation factor is binned) is simply the number of events in the anti-identified lepton control sample multiplied by the extrapolation factor derived from the  $Z$ +jets control sample. Figure 5.13 shows the extrapolation factors derived for electrons and muons.

## QCD MULTIJET BACKGROUND

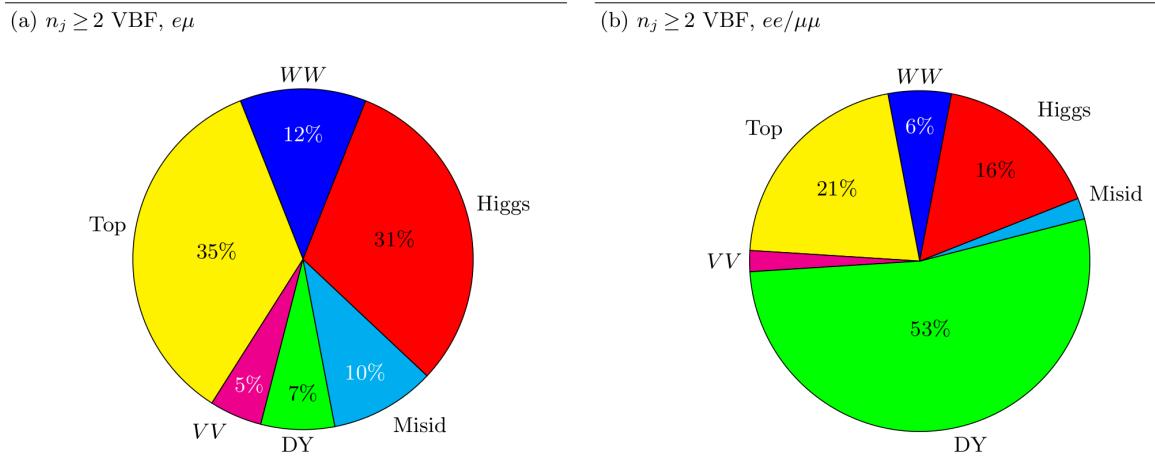

The method for estimating the multijet background is very similar to the  $W$ +jets estimation method. The control sample in this case has two anti-identified leptons but otherwise satisfies all signal region requirements. The extrapolation factor is estimated from a multijet sample and applied twice to the control sample.

### 5.5.8 BACKGROUND COMPOSITION IN FINAL SIGNAL REGION

After all of these estimation procedures, the final signal region composition can be calculated. The estimated yields are all shown in table 5.7. Figure 5.14 shows the relative percentages of the different background for the different flavor and same flavor final states. In  $e\mu$ , the leading backgrounds are top backgrounds, ggF Higgs, and SM  $WW$  production. In  $ee/\mu\mu$ , the leading background is Drell-Yan, followed by top and ggF Higgs.

**Figure 5.13:** Extrapolation factors for the  $W+jets$  estimate derived for muons (a) and electrons (b) as a function of lepton  $p_T$ [7].

**Figure 5.14:** Background composition in final VBF signal region[7].

## 5.6 SYSTEMATIC UNCERTAINTIES

There are two main types of systematic uncertainties that are assessed for the analysis. First, theoretical uncertainties associated with the various signal and background yield estimates are discussed. Then, experimental uncertainties due to detector effects are shown. Normalization uncertainties refer to uncertainties that affect the cross section of the process in question in the signal region being probed. Shape uncertainties refer to systematic uncertainties that affect the shape of the final discriminating variable (either  $m_T$  or  $O_{\text{BDT}}$ ).

### 5.6.1 THEORETICAL UNCERTAINTIES

There are four main components to theoretical uncertainties assigned to signal and background processes taken from Monte Carlo. Each one is a different source of variation in the overall acceptance for that process. The first involves variation of the QCD renormalization and factorization scales used in the calculation. In this case, the two scales are varied independently and simultaneously by factors of two high or low and quantifying the resulting variation in normalization and shape for the process. This approximates the correction to the cross section that would come from including the next order of the QCD calculation (referred to as scale uncertainty). Next, there is an uncertainty associated with the PDF set used in generating the events. The uncertainty eigenvectors for the given PDF set are studied, and the envelope of maximal variation is taken as an uncertainty. Finally, there are two uncertainties associated with the choice of MC software (referred to as PDF uncertainty). An uncertainty associated with the generator chosen for the hard scattering process is evaluated by keeping the parton showering software constant but varying the matrix element generator and taking the maximal variation as an uncertainty (referred to as the generator uncertainty). The converse variation can also be done, where the matrix element generator remains constant and the generator used for the underlying event/parton shower modeling is varied (referred to as the UE/PS uncertainty). In cases where the background is normalized in a control region, the systematic uncertainty arises from variations of the extrapolation factor  $\alpha$  between the CR and the SR, which can affect the normalization of the background in the SR.

There are two additional uncertainties that are applied to the Higgs processes as well. First, there are

	VBF $H$	ggF $H$	Top	<u>QCD</u> $WW$
Total $\sigma$	2.7	7.2	-	-
Jet binning	-	29	-	-
Scale	3.0	48	5.0	27*
Generator	4.2	-	21	12
PDF	-	3.0	-	4*
UE/PS	14	15	-	2

**Table 5.12:** Systematic uncertainties for various processes in the BDT analysis, given in units of % change in yield. Values are given for the most sensitive BDT bin (bin 3), except where noted with a \*, in which case the uncertainty affect the normalization in all BDT bins. Empty entries indicate that the uncertainty is negligible or not applicable to this background.

uncertainties assigned to the Higgs total production cross section. Then, there are uncertainties assigned based on the fact that the analysis is done in exclusive jet bins and it is possible for signal events to migrate from one bin to the next depending on the presence or absence of jets. These are assigned using the Jet Veto Efficiency (JVE) procedure[?] for ggF events and the Stewart-Tackmann (ST) method[62] for VBF production.

Table 5.12 shows how the different theory uncertainty components contribute to variation in the yields of dominant background processes and signal in the BDT analysis. Table 5.13 shows the total theory uncertainties on the backgrounds in the cut-based analysis. The  $Z/\gamma^* \rightarrow \tau\tau$  background is included here because it plays a larger role while in the BDT analysis it is negligible.

Process	Theory syst. (%)
ggF $H$	48
Top	26
<u>QCD</u> $WW$	37
$Z/\gamma^* \rightarrow \tau\tau$	6.1

**Table 5.13:** Systematic uncertainties for various processes in the cut-based VBF analysis, given in units of % change in yield. Values are given for the low  $m_{jj}$  signal region.

While the estimate for the same-flavor  $Z/\gamma^* \rightarrow \ell\ell$  background is data-driven, there is still a systematic uncertainty taken for the non-closure of the method in Monte Carlo. This is taken as the maximum of the deviation of the non-closure factor  $f_{\text{corr}}$  from unity and its uncertainty, or  $\max(|1 - f_{\text{corr}}|, \delta f_{\text{corr}})$ . For the BDT analysis, this uncertainty is 17%, while for the cut-based analysis it is 23%.

For illustration, figures 5.15 and 5.16 show the variations in the extrapolation factor from the PDF and

QCD uncertainties on the top background estimate, binned in  $m_T$ , for the cut-based analysis. In both cases, there was no significant shape uncertainty but normalization uncertainties were assigned according to the maximal variation.

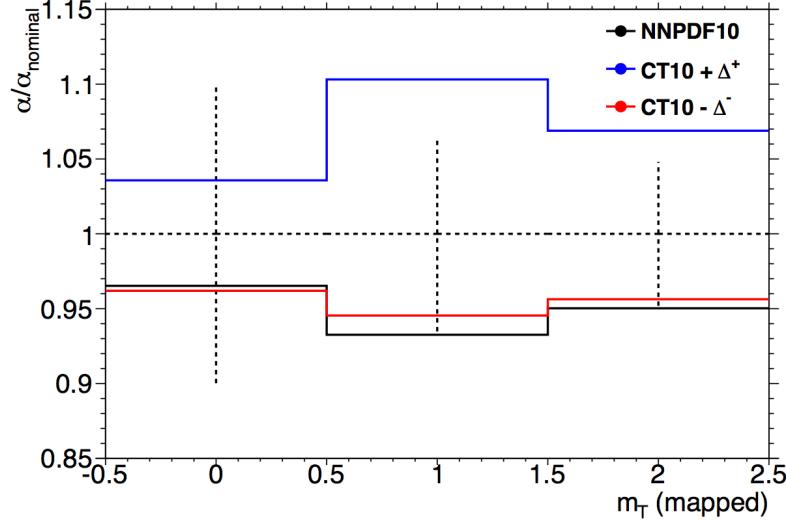

Figure 5.15: Variations in the top background extrapolation factor in the cut-based analysis due to PDF uncertainties, binned in  $m_T$ .

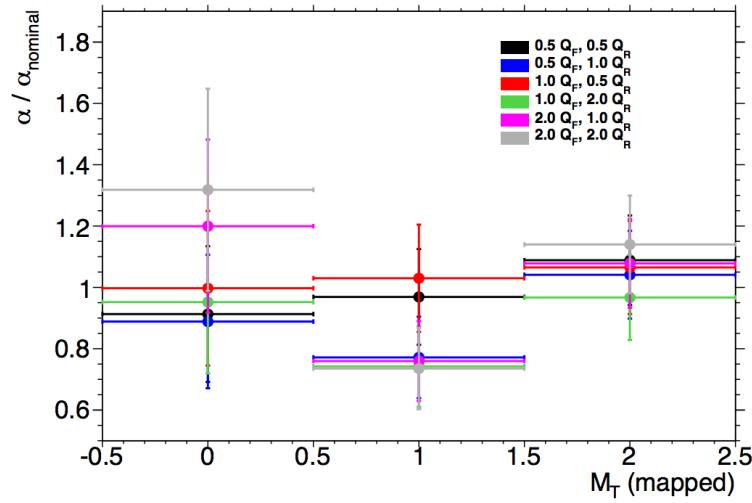

Figure 5.16: Variations in the top background extrapolation factor in the cut-based analysis due to QCD scale uncertainties, binned in  $m_T$ .

### 5.6.2 EXPERIMENTAL UNCERTAINTIES

In this analysis, the theoretical uncertainties end up being the most dominant, but there are some experimental uncertainties that make a contribution as well. The first is the uncertainty on the measured integrated luminosity, which affects backgrounds whose normalization is taken from MC and is measured to be 2.8% in the 8 TeV dataset [63]. The dominant sources of uncertainty overall are uncertainties on the jet energy scale and resolution and the  $b$ -tagging efficiency. Additional sources include lepton uncertainties on identification, resolution, and trigger efficiency, as well as uncertainties on the missing transverse momentum .

The jet energy scale uncertainty is split into several independent components, including jet-flavor dependent calorimeter response uncertainties, uncertainties on modeling of pile-up interactions, uncertainties on extrapolation from the central to forward detector regions, and MC non-closure [64]. The uncertainty on energy scale for jets used in this analysis ranges from 1% to 7% depending on the jet  $p_T$  and  $\eta$ . The jet energy resolution varies from 5% to 20%, with uncertainties ranging from 2% to 40% (the largest uncertainties occurring at the selection threshold).

The  $b$ -tagging efficiency is independently measured in data samples enriched in dileptonic decays of  $t\bar{t}$  events or in events where a muon is reconstructed in the vicinity of a jet[65, 66]. The efficiencies and their uncertainties are binned in  $p_T$  and decomposed into uncorrelated components using an eigenvector method[? ]. Uncertainties on the efficiency range from 1% to 7.8%. The uncertainty on the rate of misidentification of  $c$ -jets as  $b$ -jets ranges from 6-14%, while the uncertainty on the rate of light jet mis-tagging ranges from 9-19% depending on  $p_T$  and  $\eta$ .

The total experimental uncertainties on different signal and background components are summarized in table 5.14. They are compared to the level of other statistical and systematic uncertainties as well. Overall, the experimental uncertainties are sub-dominant compared to the statistical and theoretical uncertainties.

Sample	Total error	Stat. error	Expt. syst. err.	Theo. syst. err.
$n_j \geq 2$ VBF-enriched				
$N_{\text{sig}}$	13	-	6.8	12
$N_{\text{bkg}}$	9.2	4.7	6.4	4.5
$N_{WW}$	32	-	14	28
$N_{\text{top}}$	15	9.6	7.6	8.5
$N_{\text{misid}}$	22	-	12	19
$N_{VV}$	20	-	12	15
$N_{\tau\tau} (\text{DY})$	40	25	31	2.9
$N_{ee/\mu\mu} (\text{DY})$	19	11	15	-

**Table 5.14:** Composition of the post-fit uncertainties (in %) on the total signal ( $N_{\text{sig}}$ ), total background ( $N_{\text{bkg}}$ ), and individual background yields in the VBF analysis[7].

## 5.7 RESULTS

While the combined results of all the  $H \rightarrow WW^*$  sub-analyses will be discussed in the next chapter, this section presents the results of the VBF specific analysis and interpretations.

As table 5.7 shows, the final cut-based signal region contains 20 events in data with  $m_T < 150$  GeV, 14 coming from the  $e\mu$  channel and 6 coming from the  $ee + \mu\mu$  channel. The BDT analysis has many more candidates due to its looser selection, and the yields in each bin of  $O_{\text{BDT}}$  are shown in table 5.15.

Figure 5.17(a) shows the final distribution of data candidates compared to the expected  $m_T$  distribution for signal and background. The data are very consistent with a VBF Higgs hypothesis. Figure 5.17(b) shows where the data candidates fall in the two-dimensional binning of  $m_T$  and  $m_{jj}$  used in the fit for the cut-based analysis.

Figure 5.18 shows the distributions of  $O_{\text{BDT}}$  and  $m_T$  in the VBF BDT analysis. Again the data are quite consistent with a VBF Higgs hypothesis.

Because the cut-based result is used as a validation for the BDT analysis and the two signal regions are not fully orthogonal, it is interesting to explore which events overlap between the two analyses. Of the twenty events in the cut-based signal region, only seven were not selected by the BDT analysis, while the other thirteen also enter the BDT signal region. Figure ?? shows where the different analysis candidates lie in the  $m_{jj}$ - $m_T$  plane. This shows clearly that the advantage of the BDT analysis is that it can extract

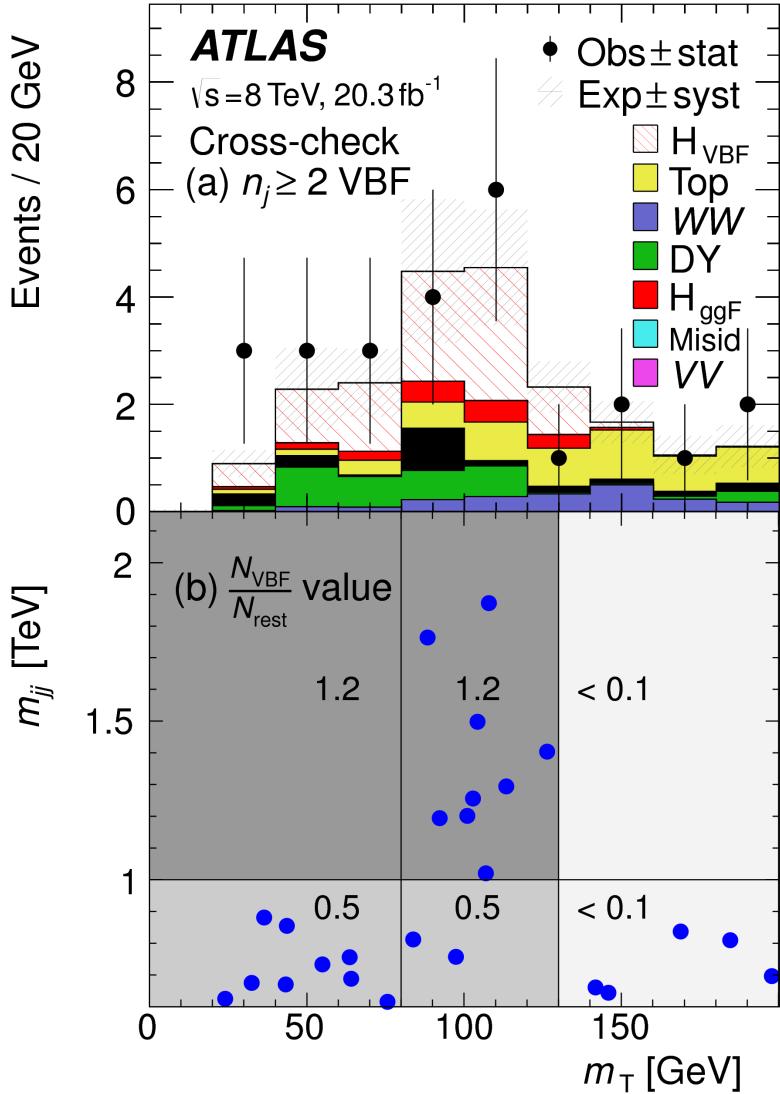

(a) Before the BDT classification

**Table 5.15:** Event selection for the VBF BDT analysis. The event yields in (a) are shown after the preselection and the additional requirements applied before the BDT classification (see text). The event yields in (b) are given in bins in  $O_{\text{BDT}}$  after the classification[7].

**Figure 5.17:** Postfit distributions in the cut-based VBF analysis. Panel (a) shows the one-dimensional  $m_T$  distribution, while (b) shows the data candidates split into the bins of  $m_T$  and  $m_{jj}$  used in the final fit[7].

signal candidates lower  $m_{jj}$  region due to its ability to recognize correlations with other variables.

While the context of these results in the broader  $H \rightarrow WW^*$  statistical analysis will be presented in the next chapter, the significance of the VBF observation can be shown here. In the BDT analysis, the expected signal significance was  $2.7\sigma$ , while the observed significance was  $3.1\sigma$ . In the cut-based analysis, the expected significance was  $2.1\sigma$  and the observed significance was  $3.0\sigma$ . The compatibility between these two results can be evaluated by computing the probability of observing a larger difference

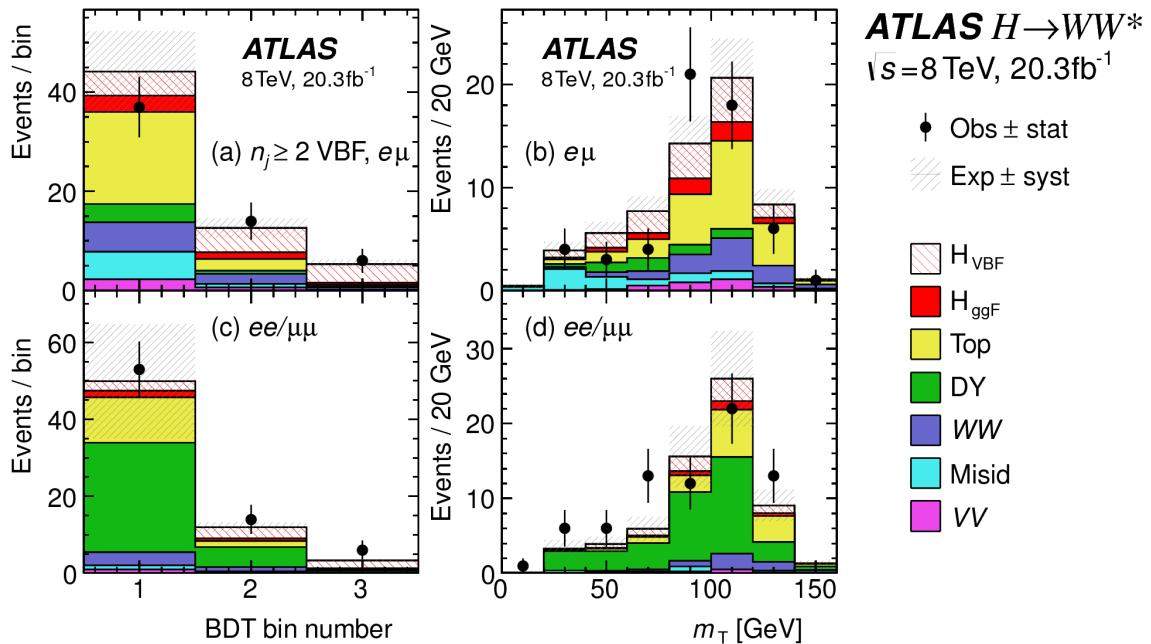

Figure 5.18: Postfit distributions in the BDT VBF analysis[7].

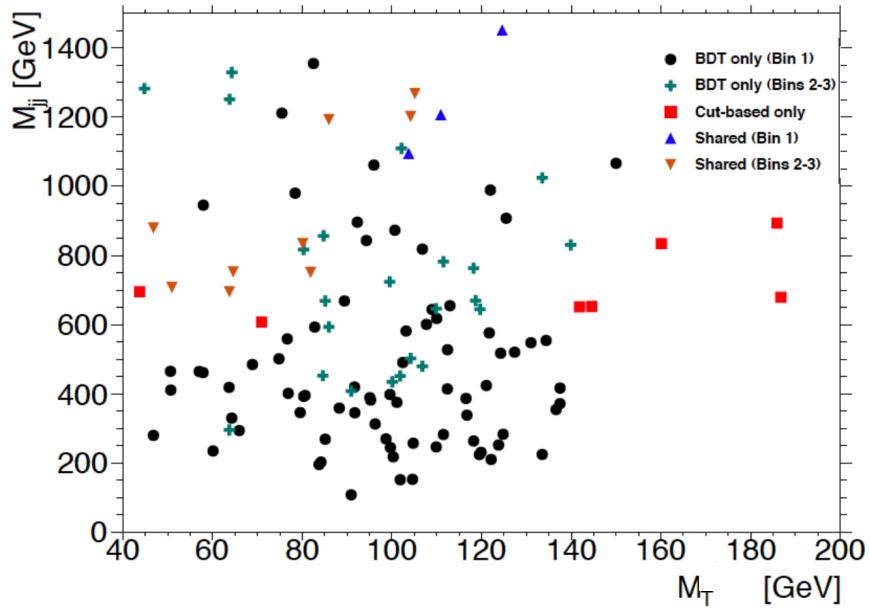

Figure 5.19: Overlap between cut-based and BDT VBF signal region candidates in the  $m_{jj}$ - $m_T$  plane.

in  $Z_0$  values than the one measured. Using toy Monte Carlo with the ggF signal strength fixed to unity and considering only statistical uncertainties, this probability is computed to be 79%, indicating good agreement between the analyses.

This result represents the first observation of the vector boson fusion production of a Higgs boson.

*The feeling is less like an ending than just another  
starting point.*

## Combined Run I $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$ results

### 6.1 INTRODUCTION

In the final statistical analysis of  $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$ , the dedicated gluon-gluon fusion and vector boson fusion sensitive signal regions are all combined into a single fit to determine the main parameters of interest, the Higgs signal strength  $\mu$  and mass  $m_H$ . Therefore, while the specific requirements applied for the VBF sensitive analysis are discussed in chapter 5, the final measurement of these parameters can only be discussed in combination with the results of the ggF dedicated analysis. For example, because ggF Higgs production is considered a background in the VBF analysis, the ggF dedicated signal regions can actually constrain the normalization of this background in the VBF dedicated region.

This chapter presents the combined interpretation of results in the  $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$  analysis

SR category $i$				Fit var.	
$n_j$ , flavor	$\otimes m_{\ell\ell}$	$\otimes p_T^{\ell 2}$	$\otimes \ell_2$		
$n_j = 0$	$e\mu$	$\otimes [10, 30, 55]$	$\otimes [10, 15, 20, \infty]$	$\otimes [e, \mu]$	$m_T$
	$ee/\mu\mu$	$\otimes [12, 55]$	$\otimes [10, \infty]$		$m_T$
$n_j = 1$	$e\mu$	$\otimes [10, 30, 55]$	$\otimes [10, 15, 20, \infty]$	$\otimes [e, \mu]$	$m_T$
	$ee/\mu\mu$	$\otimes [12, 55]$	$\otimes [10, \infty]$		$m_T$
$n_j \geq 2$ ggF	$e\mu$	$\otimes [10, 55]$	$\otimes [10, \infty]$		$m_T$
$n_j \geq 2$ VBF	$e\mu$	$\otimes [10, 50]$	$\otimes [10, \infty]$		$O_{BDT}$
	$ee/\mu\mu$	$\otimes [12, 50]$	$\otimes [10, \infty]$		$O_{BDT}$

**Table 6.1:** All signal regions definitions input into final statistical fit[7].

for gluon fusion and vector boson fusion Higgs production. First, the results of the dedicated gluon fusion search are presented. Then, a comparison of the individual production mode signal strengths ( $\mu_{ggF}$  and  $\mu_{VBF}$  and a measurement of the combined signal strength ( $\mu$ ) are shown. Subsequently, the measured values of the Higgs couplings to fermions and vector bosons is presented. Finally, the cross section measurement for ggF and VBF production are shown.

## 6.2 RESULTS OF DEDICATION GLUON FUSION $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$ SEARCH

The details of the dedicated gluon fusion  $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$  search are not discussed in this thesis and instead left to more comprehensive sources[7]. However, a brief summary of the results are essential for describing the results of the full analysis and interpreting the results of the dedicated VBF search in this broader context.

Table 6.1 shows the individual signal regions that were input into the final statistical fit. The ggF dedicated bins use  $m_T$  as their discriminating variable and are separated into bins of  $p_T$  of the subleading lepton as well. The VBF dedicated bin uses the  $O_{BDT}$  distribution as its final discriminant.

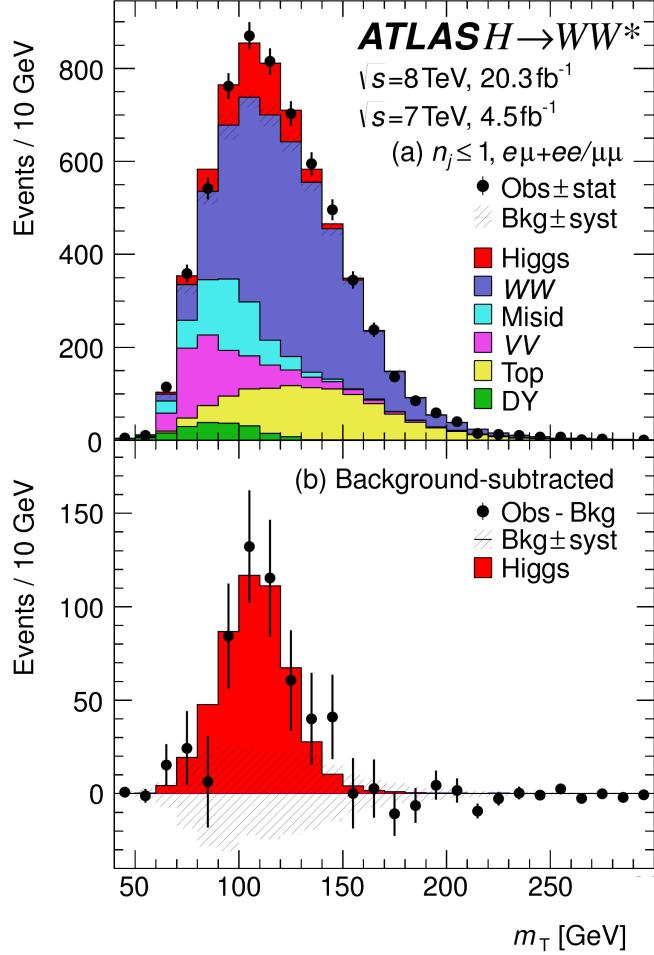

Table 6.2 shows the yields in the various signal regions in both data and expected signal and back-

grounds. The yields for signal and background are all scaled according to the final normalizations calculated in the fit.

	$N_{\text{obs}}$	$N_{\text{bkg}}$	$N_{\text{ggF}}$	$N_{\text{VBF}}$
$n_j = 0$	3750	$3430 \pm 90$	$300 \pm 50$	$8 \pm 4$
$n_j = 1$	1596	$1470 \pm 40$	$102 \pm 26$	$17 \pm 5$
$n_j \geq 2, \text{ggF } e\mu$	1017	$960 \pm 40$	$37 \pm 11$	$13 \pm 1.4$
$n_j \geq 2, \text{VBF}$	130	$99 \pm 9$	$7.7 \pm 2.6$	$21 \pm 3$

**Table 6.2:** Post-fit yields in the different ggF and VBF dedicated signal regions[7].

Figure 6.1 shows the final post-fit  $m_T$  distribution in the  $n_j \leq 1$  regions. The data are very consistent with the hypothesis of ggF Higgs production.

**Figure 6.1:** Post-fit  $m_T$  distribution in the  $n_j \leq 1$  regions[7].

These yields are used as input, along with the VBF results in chapter 5, for the physical interpretation of results presented in subsequent sections.

### 6.3 SIGNAL STRENGTH MEASUREMENTS IN ggF AND VBF PRODUCTION

When all of the signal regions are combined in the fit, there can be a combined measurement of the signal strength as well as the individual ggF and VBF signal strengths. The combined signal strength is the ratio of the sum of the gluon fusion and VBF cross sections to the theory prediction, or a singal strength for the total Higgs production cross section that this analysis is sensitive to. The final measured combined signal strength  $\mu$  is measured shown in equation 6.1.

$$\begin{aligned} \mu &= 1.09 \quad {}^{+0.16}_{-0.15} \text{ (stat.)} \quad {}^{+0.08}_{-0.07} \left( \begin{array}{l} \text{expt} \\ \text{syst} \end{array} \right) \quad {}^{+0.15}_{-0.12} \left( \begin{array}{l} \text{theo} \\ \text{syst} \end{array} \right) \quad \pm 0.03 \left( \begin{array}{l} \text{lumi} \\ \text{syst} \end{array} \right) \\ &= 1.09 \quad {}^{+0.16}_{-0.15} \text{ (stat)} \quad {}^{+0.17}_{-0.14} \text{ (syst)} \\ &= 1.09 \quad {}^{+0.23}_{-0.21}. \end{aligned} \tag{6.1}$$

Figure 6.2 gives the best fit signal strength  $\hat{\mu}$  as a function of hte hypothesized Higgs mass. The value at 125.36 GeV corresponds to the  $\mu$  quoted in equation 6.1. This value of the Higgs mass is used because it is the most precise mass measurement from ATLAS, a result of the combined  $\gamma\gamma$  and  $ZZ$  mass measurements[? ].

As explained in chapter 3, a probability  $p_0$  can be computed using the test statistic  $q_0$  to quantify the probability that the background could fluctuate to produce an excess at least as large as the one observed in the data. The local  $p_0$  value is shown in figure 6.3 as a function of  $m_H$ . The minimum  $p_0$  value is at  $m_H = 130$  GeV and coresponds to a significance of  $6.1\sigma$ . The curve is relatively flat and the significance is the same at 125.36 GeVwithin the quoted precision. The expected significance for a signal with strength  $\mu = 1.0$  is  $5.8\sigma$ . This represents the first discovery level significance measurement in the  $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$  analysis.

All the results presented so far in this section have been for the combined gluon fusion and VBF production modes. However, each signal strength can be calculated separately in the likelihood as well. There are two ways to do this. First, the likelihood can be parameterized in terms of a single parameter,

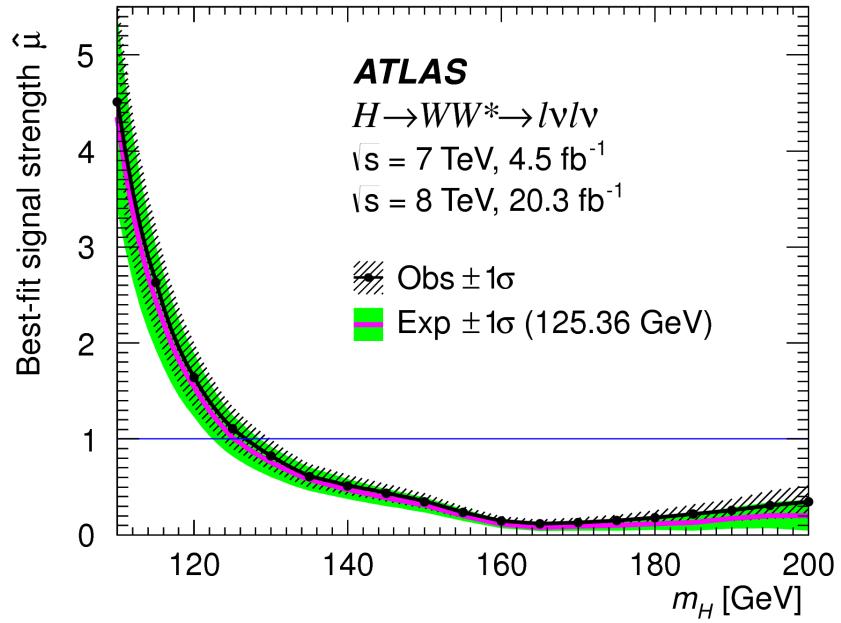

Figure 6.2: Best fit signal strength  $\hat{\mu}$  as a function of hypothesized  $m_H$ [7].

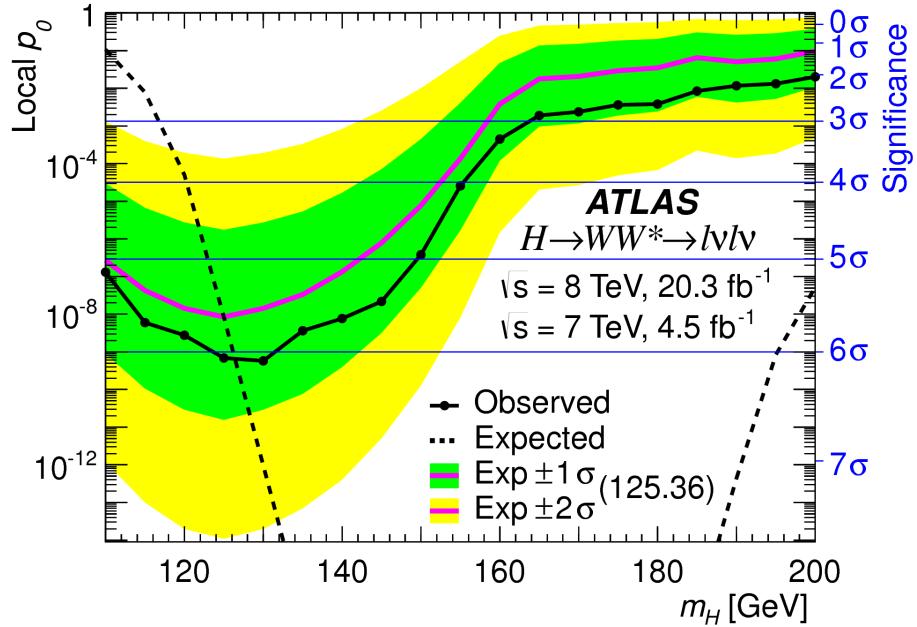

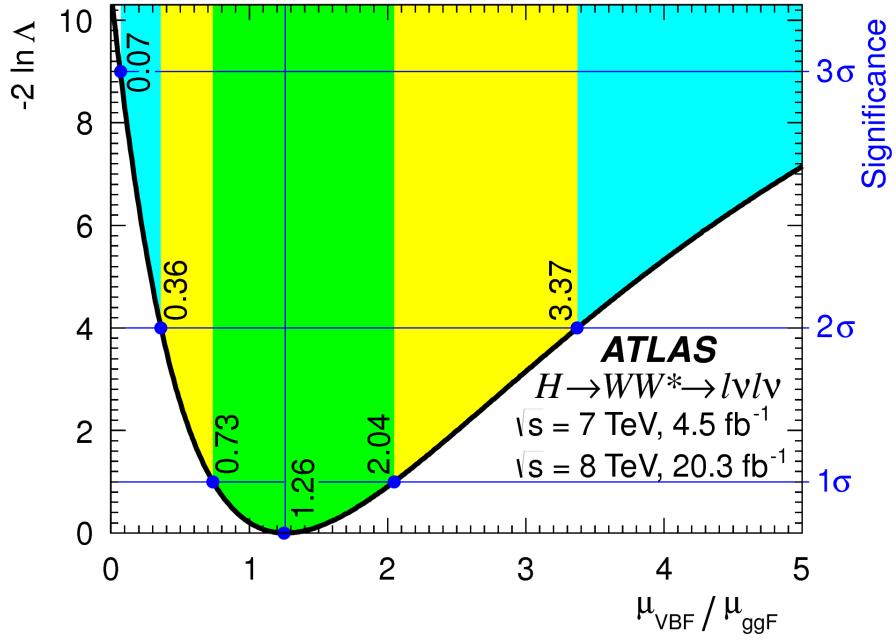

Figure 6.3: Local  $p_0$  as a function of  $m_H$ [7].

the ratio of the VBF and gluon fusion signal strengths. With this method, the significance of the VBF observation can be evaluated. Figure 6.4 shows the likelihood as a function of the ratio  $\mu_{\text{VBF}}/\mu_{\text{ggF}}$ .

**Figure 6.4:** Likelihood as a function of  $\mu_{\text{VBF}} / \mu_{\text{ggF}}$ [7].

The best fit value of the ratio of signal strengths is shown in equation 6.2. Within the quoted uncertainties, it is consistent with a ratio of unity.

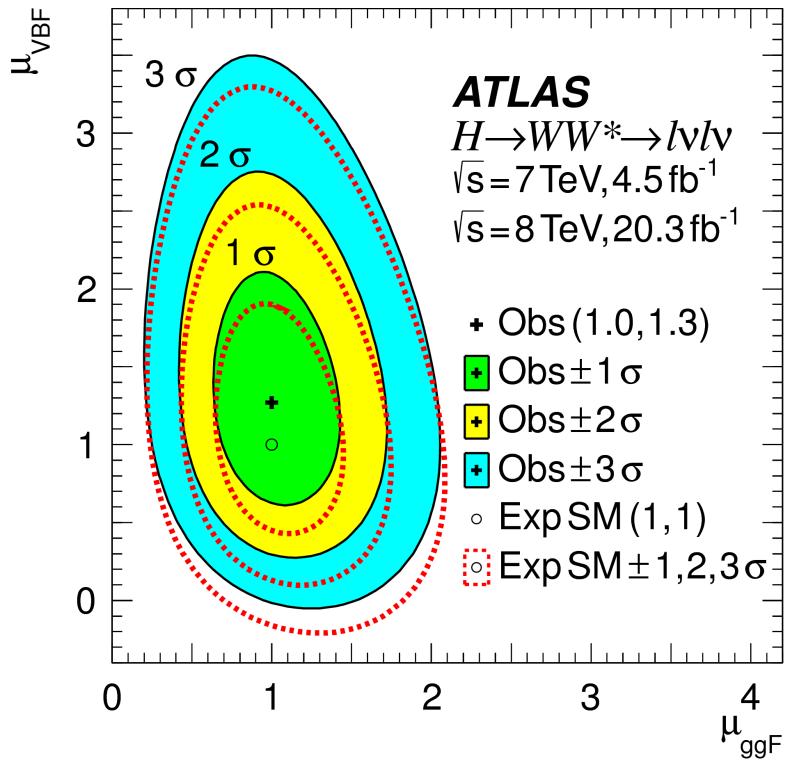

$$\frac{\mu_{\text{VBF}}}{\mu_{\text{ggF}}} = 1.26^{+0.61} (\text{stat.})^{+0.50} (\text{syst.}) = 1.26^{+0.79}_{-0.53} \quad (6.2)$$

The null hypothesis for VBF production corresponds to a ratio of  $\mu_{\text{VBF}} / \mu_{\text{ggF}} = 0$ . The likelihood in figure 6.4 gives a significance of  $3.2\sigma$  at  $\mu_{\text{VBF}} / \mu_{\text{ggF}} = 0$ , as quoted in chapter 5.

In addition to the ratio of signal strengths, each signal strength can be varied independently in the likelihood as well. Figure 6.5 shows the two dimensional likelihood scan in the  $\mu_{\text{ggF}}-\mu_{\text{VBF}}$  plane. The best fit values of the two signal strengths are shown in equation 6.3. Both are consistent with unity within their uncertainties.

$$\begin{aligned} \mu_{\text{ggF}} &= 1.02 \pm 0.19^{+0.22}_{-0.18} = 1.02^{+0.29}_{-0.26} \\ \mu_{\text{VBF}} &= 1.27 \pm 0.44^{+0.29}_{-0.40} = 1.27^{+0.53}_{-0.45}. \end{aligned} \quad (6.3)$$

(stat.) (syst.)

**Figure 6.5:** Likelihood scan as a function of  $\mu_{\text{VBF}}$  and  $\mu_{\text{ggF}}$  [7].

#### 6.4 MEASUREMENT OF HIGGS COUPLINGS TO VECTOR BOSONS AND FERMIONS

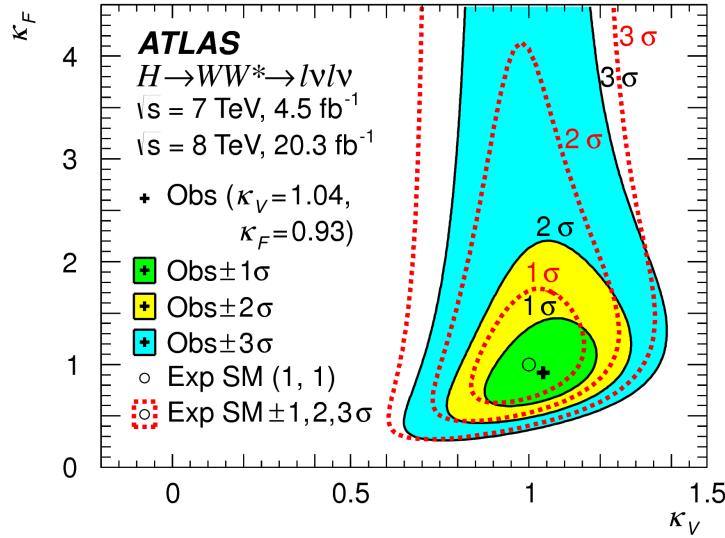

Similar to the parameterization of signal strength, the couplings of the Higgs to fermions and bosons can also be parameterized. The parameter of interest in this case is  $\kappa$ , or the ratio of the measured coupling to the standard model expectation. Both the fermion and boson couplings have these so-called scale factors,  $\kappa_F$  for fermions and  $\kappa_V$  for bosons. Gluon fusion production is sensitive to the fermion couplings through the top quark loops in its production, while VBF production is sensitive to the vector boson couplings in its production. Both modes are sensitive to the vector boson couplings in their decays. The signal strengths will have dependence on the coupling scale factors as described in equation 6.4[2].

$$\begin{aligned} \mu_{\text{ggF}} &\propto \frac{\kappa_F^2 \cdot \kappa_V^2}{(\mathcal{B}_{H \rightarrow f\bar{f}} + \mathcal{B}_{H \rightarrow gg}) \kappa_F^2 + (\mathcal{B}_{H \rightarrow VV}) \kappa_V^2} \\ \mu_{\text{VBF}} &\propto \frac{\kappa_V^4}{(\mathcal{B}_{H \rightarrow f\bar{f}} + \mathcal{B}_{H \rightarrow gg}) \kappa_F^2 + (\mathcal{B}_{H \rightarrow VV}) \kappa_V^2}. \end{aligned} \quad (6.4)$$

Figure 6.6 shows the two-dimensional likelihood scan of  $\kappa_F$  and  $\kappa_V$ . The best-fit values are given in equation 6.5. The best-fit values are consistent with unity within their uncertainties.

$$\begin{aligned} \kappa_F &= 0.93 & +0.24 & +0.21 & = 0.93 & +0.32 \\ && -0.18 & -0.14 && -0.23 \\ \kappa_V &= 1.04 & +0.07 & +0.07 & = 1.04 & \pm 0.11. \end{aligned} \quad (6.5)$$

(stat.) (syst.)

**Figure 6.6:** Likelihood scan as a function of  $\kappa_F$  and  $\kappa_V$ [7].

## 6.5 HIGGS PRODUCTION CROSS SECTION MEASUREMENT

Another measurement that comes naturally from the signal strength numbers quoted earlier is the production cross section and 7 and 8 TeV for both gluon fusion and VBF production. The general equation for calculating the cross section is given in equation 6.6.

$$\begin{aligned} (\sigma \cdot \mathcal{B}_{H \rightarrow WW^*})_{\text{obs}} &= \frac{(N_{\text{sig}})_{\text{obs}}}{\mathcal{A} \cdot \mathcal{C} \cdot \mathcal{B}_{WW \rightarrow \ell\nu\ell\nu}} \cdot \frac{1}{\int L dt} \\ &= \hat{\mu} \cdot (\sigma \cdot \mathcal{B}_{H \rightarrow WW^*})_{\text{exp}} \end{aligned} \quad (6.6)$$

$(N_{\text{sig}})_{\text{obs}}$  is the number of events observed in data.  $\mathcal{A}$  is the geometric and kinematic acceptance of the detector, while  $\mathcal{C}$  is the efficiency of the signal region selection for events that are reconstructed in the detector. The branching ratio of a  $WW$  system to leptons must also be divided out. The production cross section depends on the center of mass energy and the production mode desired (gluon fusion or VBF), and so three separate cross section measurements are quoted in equation 6.7.

$$\begin{aligned} \sigma_{\text{ggf}}^{\text{7TeV}} \cdot \mathcal{B}_{H \rightarrow WW^*} &= 2.0 \pm 1.7 {}^{+1.2}_{-1.1} = 2.0 {}^{+2.1}_{-2.0} \text{ pb} \\ \sigma_{\text{ggf}}^{\text{8TeV}} \cdot \mathcal{B}_{H \rightarrow WW^*} &= 4.6 \pm 0.9 {}^{+0.8}_{-0.7} = 4.6 {}^{+1.2}_{-1.1} \text{ pb} \\ \sigma_{\text{VBF}}^{\text{8TeV}} \cdot \mathcal{B}_{H \rightarrow WW^*} &= 0.51 {}^{+0.17}_{-0.15} {}^{+0.13}_{-0.08} = 0.51 {}^{+0.22}_{-0.17} \text{ pb.} \end{aligned} \quad (6.7)$$

(stat.) (syst.)

The predicted cross section values for gluon fusion are  $3.3 \pm 0.4$  pb at 7 TeV and  $4.2 \pm 0.5$  pb at 8 TeV, consistent with the measured values within their uncertainties. For vector boson fusion, the predicted cross section is  $0.35 \pm 0.02$  pb, again consistent with the measured value.

## 6.6 CONCLUSION

The combined analysis of the gluon fusion and vector boson fusion processes in  $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$  in the 7 and 8 TeV datasets has yielded the first discovery level significance for Higgs production in this decay channel. Additionally, precise measurements of the couplings to vector bosons and fermions are given. Finally, signal strengths and cross sections for each production mode are measured. Figure 6.7 shows the  $H \rightarrow WW^* \rightarrow \ell\nu\ell\nu$  measurements in comparison with other Higgs decay channels in ATLAS. The measurement of signal strength from this channel remains the most sensitive in both the gluon fusion and VBF production modes for the Run 1 dataset.
